## Acknowledgements

This dissertation was made possible by the mentorship, collaboration, and friendship of many people. I am so thankful to be surrounded by such supportive and helpful mentors, peers, and friends that have made navigating through graduate school and finishing this dissertation an enjoyable experience. Specifically, I am thankful for the incredible mentorship of my advisor and committee chair, Dr. Nick Smith, who provided invaluable insight and tools that have helped shape me into the plant ecophysiological I claim to be today. I am also indebted to my committee members, Drs. Aimée Classen, Natasja van Gestel, Dylan Schwilk, and Lindsey Slaughter, for useful feedback, invaluable support, and encouragement as I planned and implemented experiments.

I am also thankful for past and present members of the EcoHealth lab for encouragement, support, and extracurricular activities that made time inside and outside the lab enjoyable and memorable. Particular thanks go to Dr. Lizz Waring, Dr. Xiulin Gao, Helen Scott, and Risa McNellis, Billi Jean Petermann, and the late Dr. Kris Petterson, all of whom were invaluable to helping me navigate my first year. I am especially thankful for the mentorship and friendship of Dr. Lizz Waring, as our weekly coffee chats were instrumental for helping me feel welcome in Lubbock and acclimate to life as a graduate student. I am also grateful for the friendship of Billi Jean Petermann and the late Dr. Kris Petterson for their encouragement and willingness to discuss microbial symbioses over coffee on random Saturday mornings.

Additional thanks go out to Isa Beltran, Snehanjana Chatterjee, Jeff Chi-

eppa, Peter Eludini, Zinny Ezekannagha, Hannah German, Eve Gray, Monika Kelley, Azaj Mahmud, Jorge Ochoa, Brad Posch, Avery Schoenherr, Christine Vanginault, and Jose Villeda for help with experiments or for lending an ear over puzzling results. I am also thankful for collaborators Dr. Christy Goodale and Dave Frey, who provided invaluable insight for the second experimental chapter.

I would like to thank my undergraduate advisor, Dr. Janice Krumm, for continued mentorship and friendship and for insightful advice about navigating graduate school, but most of all for helping me realize my career aspirations and pushing me to pursue this endeavor. Additional thanks go out to my family, particularly my parents, partner, and dog for continued support and distractions outside the lab. The experiments included here would not have been possible without their emotional and monetary support.

This work was made possible from funding by the NSF, USDA, Braun and Gresham, PLLC., and was a contribution to the LEMONTREE (Land Ecosystem Models based On New Theory, obseRvations and ExperimEnts) project. The LEMONTREE project is funded through the generosity of Eric and Wendy Schmidt by recommendation of the Schmidt Futures programme and the Imperial College initiative on Grand Challenges in Ecosystems and the Environment. This work was also funded by graduate student research awards from Texas Tech University and the Botanical Society of America.

I have inevitably missed mentioning folks that were instrumental to the completion of these experiments and contributed to my development as a plant ecophysiological. Please know that I am grateful and appreciative of our interactions.

## Abstract

Photosynthesis is the largest carbon flux between the atmosphere and terrestrial biosphere and is constrained by ecosystem nutrient cycle dynamics, which causes terrestrial biosphere models to be sensitive to the formulation of photosynthetic processes. Terrestrial biosphere models exhibit high divergence in simulated carbon and nitrogen fluxes under future environmental conditions, which may be due to uncertainty in the acclimation response of photosynthetic processes to environmental change. Photosynthetic least-cost theory provides a promising framework for understanding effects of climatic and edaphic factors on photosynthetic acclimation responses to changing environments. Yet, empirical tests of the theory are rare, limiting our ability to assess whether the theory is suitable for implementation in next-generation terrestrial biosphere models.

Here, I present four experiments designed to test assumptions of photosynthetic least-cost theory. Experiment chapters are flanked by a general introduction chapter and conclusions chapter. The first experimental chapter quantifies structural carbon costs to acquire nitrogen in *Glycine max* and *Gossypium hirsutum* grown under four nitrogen fertilization levels and four light availability levels in a full factorial greenhouse experiment. I find that carbon costs to acquire nitrogen in both species increase with increasing light availability and decrease with increasing fertilization, though responses to fertilization in *G. max* were markedly less than *G. hirsutum*. The second experimental chapter quantifies leaf nitrogen and photosynthetic traits in upper canopy leaves of deciduous trees growing in a 9-year nitrogen-by-sulfur field manipulation experiment. I find evidence for nitrogen-

water use tradeoffs with increasing soil nitrogen availability, evidenced through a negative relationship between leaf nitrogen content and ratio of leaf intercellular CO<sub>2</sub> concentration to atmospheric CO<sub>2</sub> concentration (leaf  $C_i:C_a$ ) and stronger increase in leaf nitrogen content with increasing soil nitrogen availability than leaf  $C_i:C_a$ . The third experiment investigates variance in leaf nitrogen content across a climate and soil resource availability gradient in Texan grasslands, showing that effects of soil resource availability and climate on leaf nitrogen content are driven by changes in leaf  $C_i:C_a$ . Finally, the fourth experiment quantifies leaf and whole plant acclimation responses in *G. max* grown under two atmospheric CO<sub>2</sub> levels, with and without inoculation with *Bradyrhizobium japonicum*, and across nine nitrogen fertilization treatments in a full factorial growth chamber experiment. I find that leaf acclimation responses to CO<sub>2</sub> were independent of soil nitrogen fertilization and inoculation treatment, though increased whole plant growth under elevated CO<sub>2</sub> was enhanced with increasing soil nitrogen fertilization and in inoculated pots under low nitrogen fertilization.

Experiments included in this dissertation provide consistent support for patterns expected from photosynthetic least-cost theory. The use of multiple experimental approaches allowed me to examine mechanisms driving patterns expected from the theory and investigate whether these patterns occur in the field across environmental gradients. Findings from these chapters challenge common paradigms in plant ecophysiology, providing empirical evidence suggesting that including photosynthetic least-cost frameworks in terrestrial biosphere models may improve the longstanding observed divergence in simulated outcomes across terrestrial biosphere model products.

## List of Tables

2.1	Analysis of variance results exploring species-specific effects of light availability, nitrogen fertilization, and their interactions on carbon costs to acquire nitrogen, whole-plant nitrogen biomass, and root carbon biomass . . . . .	16
2.2	Analysis of variance results exploring effects of light availability, nitrogen fertilization, and their interactions on <i>G. max</i> root nodule biomass and the ratio of root nodule biomass to root biomass . . . . .	23
2.3	Slopes of the regression line describing the relationship between each dependent variable and nitrogen fertilization at each light level	24
3.1	Effects of soil nitrogen availability, soil pH, and species on leaf nitrogen content per unit leaf area, leaf nitrogen content per unit leaf mass, and leaf mass per unit leaf area . . . . .	51
3.2	Effects of soil nitrogen availability, soil pH, species, and $N_{\text{area}}$ on net photosynthesis, the maximum rate of Rubisco carboxylation, the maximum rate of RuBP regeneration, and the ratio of the maximum rate of RuBP regeneration to the maximum rate of Rubisco carboxylation . . . . .	54
3.3	Effects of soil nitrogen availability, soil pH, and species on the proportion of leaf nitrogen content allocated to photosynthesis, Rubisco, bioenergetics, and structure . . . . .	57

3.4 Effects of soil nitrogen availability, soil pH, species, and $N_{\text{area}}$ on $\chi$ , photosynthetic nitrogen use efficiency, leaf nitrogen content per unit $\chi$ , and maximum Rubisco carboxylation rate per unit $\chi$ . . . . .	60
4.1 Site locality information, sampling year, 2006-2020 mean annual precipitation, mean annual temperature, and water holding capacity	80
4.2 Effects of soil moisture, soil nitrogen availability, and plant functional group on $\beta$ . . . . .	89
4.3 Effects of soil moisture, soil nitrogen availability, and plant functional group on leaf $C_i:C_a$ . . . . .	93
4.4 Effects of soil moisture, soil nitrogen availability, plant functional group, and leaf $C_i:C_a$ on leaf nitrogen content per unit leaf area, leaf nitrogen content per unit leaf biomass, and leaf biomass per unit leaf area . . . . .	97
4.5 Structural equation model results investigating direct effects of climatic and soil resource availability on leaf nitrogen content . . . . .	100
5.1 Effects of soil nitrogen fertilization, inoculation, and CO <sub>2</sub> treatments on leaf nitrogen content per unit leaf area, leaf nitrogen content per unit leaf mass, leaf mass per unit leaf area, and chlorophyll content per unit leaf area . . . . .	131

5.2	Effects of soil nitrogen fertilization, inoculation, and CO <sub>2</sub> on the maximum rate of Rubisco carboxylation, the maximum rate of RuBP regeneration, dark respiration, the ratio of the maximum rate of RuBP regeneration to the maximum rate of Rubisco carboxylation, stomatal conductance, and stomatal limitation . . . . .	135
5.3	Effects of soil nitrogen fertilization, inoculation, and CO <sub>2</sub> on the fraction of leaf nitrogen allocated to Rubisco, bioenergetics, light harvesting proteins, photosynthesis, and structure . . . . .	139
5.4	Effects of CO <sub>2</sub> , fertilization, and inoculation on total leaf area, whole plant biomass, carbon costs to acquire nitrogen, belowground carbon biomass, and whole plant nitrogen biomass . . . . .	143
5.5	Effects of CO <sub>2</sub> , fertilization, and inoculation on root nodule biomass, plant investments in symbiotic nitrogen fixation, and percent nitrogen fixed from the atmosphere . . . . .	147
A1	Summary table containing volumes of compounds used to create modified Hoagland's solutions for each soil nitrogen fertilization treatment . . . . .	205
A2	Analysis of variance results exploring species-specific effects of light availability, nitrogen fertilization, and their interactions on the ratio of whole plant biomass to pot volume . . . . .	206
A3	Slopes of the regression line describing the relationship between each dependent variable and nitrogen fertilization at each light level	207

B1	Sample sizes of each species, abbreviated by their USDA NRCS PLANTS database code, within each plot at each site . . . . .	209
B2	Analysis of variance results exploring the linear effect of leaf temperature on net photosynthesis rate and stomatal conductance measured at 400 $\mu\text{mol mol}^{-1}$ CO <sub>2</sub> . . . . .	210
B3	Second order log-polynomial regression coefficients that described the effect of leaf temperature on net photosynthesis and stomatal conductance measured at 400 $\mu\text{mol mol}^{-1}$ CO <sub>2</sub> . . . . .	211
B4	Mean, standard error, and 95% confidence interval ranges of soil nitrogen availability estimates across all measured plots . . . . .	212
C1	List of sampled species and their plant functional group assignment	216
C2	List of sampled species and their plant functional group assignment (cont.) . . . . .	217
C3	Model selection results for soil moisture and vapor pressure deficit	218
D1	Summary table containing volumes of compounds used to create modified Hoagland's solutions for each soil nitrogen fertilization treatment . . . . .	220

1                           **Chapter 1**  
2                           **Introduction**

3         Photosynthesis represents the largest carbon flux between the atmosphere  
4     and biosphere, and is regulated by complex ecosystem carbon and nutrient cy-  
5     cles (Hungate et al. 2003; IPCC 2021). As a result, the inclusion of robust,  
6     empirically tested representations of photosynthetic processes is critical in order  
7     for terrestrial biosphere models to accurately and reliably simulate carbon and  
8     nutrient fluxes between the atmosphere and terrestrial biosphere (Oreskes et al.  
9     1994; Smith and Dukes 2013; Prentice et al. 2015; Wieder et al. 2015). De-  
10  spite evidence that the inclusion of coupled carbon and nutrient cycles can reduce  
11  model uncertainty, widespread divergence in predicted carbon and nutrient fluxes  
12  is still apparent across model products (Friedlingstein et al. 2014; Arora et al.  
13  2020; Davies-Barnard et al. 2020). Divergence in predicted carbon and nutrient  
14  fluxes across terrestrial biosphere models may be due to an incomplete under-  
15  standing of how plants acclimate to changing environments (Smith and Dukes  
16  2013; Davies-Barnard et al. 2020), as terrestrial biosphere models are sensitive to  
17  the formulation of photosynthetic processes (Bonan et al. 2011; Ziehn et al. 2011;  
18  Booth et al. 2012; Smith et al. 2016; Smith et al. 2017; Rogers et al. 2017).

19         Many terrestrial biosphere models predict leaf-level photosynthesis through  
20  linear relationships between area-based leaf nitrogen content and the maximum  
21  rate of Ribulose-1,5-bisphosphate carboxylase/oxygenase (“Rubisco”), following  
22  the idea that large fractions of leaf nitrogen content are allocated to the con-  
23  struction and maintenance of Rubisco and other photosynthetic enzymes (Evans

24 1989). The inclusion of coupled carbon and nutrient cycles in terrestrial bio-  
25 sphere models (Shi et al. 2016; Braghieri et al. 2022) allows for the prediction  
26 of leaf nitrogen content through soil nitrogen availability, which causes models to  
27 indirectly predict photosynthetic processes through shifts in soil nitrogen avail-  
28 ability (Smith et al. 2014; Lawrence et al. 2019). While these patterns are  
29 commonly observed in ecosystems globally (Brix 1971; Evans 1989; Firn et al.  
30 2019; Liang et al. 2020), this formulation does not allow for the prediction of  
31 leaf and whole plant acclimation responses to changing environments (Smith and  
32 Dukes 2013; Rogers et al. 2017; Harrison et al. 2021), and suggests that constant  
33 leaf nitrogen-photosynthesis relationships are ubiquitous across ecosystems.

34 Photosynthetic least-cost theory (Prentice et al. 2014; Wang et al. 2017;  
35 Smith et al. 2019; Paillassa et al. 2020; Scott and Smith 2022; Harrison et al.  
36 2021) provides a framework for predicting leaf and whole plant acclimation re-  
37 sponds to environmental change. The theory, which unifies optimal coordination  
38 (Chen et al. 1993; Maire et al. 2012) and least-cost (Wright et al. 2003) theo-  
39 ries, posits that plants optimize leaf net photosynthesis rates by minimizing the  
40 summed cost of nutrient and water use. Minimized costs of nutrient and water use  
41 at the leaf level optimizes leaf photosynthesis by allowing net photosynthesis to be  
42 equally co-limited by the maximum rate of Rubisco carboxylation and the max-  
43 imum rate of Ribulose-1,5-bisphosphate (RuBP) regeneration (Chen et al. 1993;  
44 Maire et al. 2012). The theory indicates that costs of nutrient and water use  
45 are substitutable such that, in a given environment, optimal photosynthesis rates  
46 can be achieved by sacrificing inefficient use of a relatively more abundant (and  
47 less costly to acquire) resource for more efficient use of a relatively less abundant

48 (and more costly to acquire) resource. This may result in changes in the ratio of  
49 the cost to acquire and use nutrients relative to the cost to acquire and use water  
50 (i.e.,  $\beta$ ) across environmental gradients. For example, plants may respond to an  
51 increase in soil nitrogen availability by increasing leaf nitrogen allocation and de-  
52 creasing stomatal conductance, allowing a given net photosynthesis rate achieved  
53 through reduced nitrogen use efficiency and increased water use efficiency. The  
54 theory predicts that  $\beta$  is positively correlated with the ratio of intercellular CO<sub>2</sub>  
55 to atmospheric CO<sub>2</sub> (leaf C<sub>i</sub>:C<sub>a</sub>), which is determined by factors that influence  
56 leaf nutrient demand to build and maintain photosynthetic enzymes, such as at-  
57 mospheric CO<sub>2</sub>, temperature, vapor pressure deficit, or light availability (Prentice  
58 et al. 2014; Wang et al. 2017; Smith et al. 2019; Stocker et al. 2020). Thus,  
59 photosynthetic least-cost theory provides a promising framework for understand-  
60 ing integrated plant acclimation responses to changes in climatic and edaphic  
61 gradients.

62 Optimality models that use patterns expected from photosynthetic least-  
63 cost theory have been developed for both C<sub>3</sub> (Wang et al. 2017; Smith et al. 2019;  
64 Stocker et al. 2020) and more recently for C<sub>4</sub> species (Scott and Smith 2022).  
65 Such models show broad agreement with patterns observed across environmental  
66 gradients (Smith et al. 2019; Stocker et al. 2020; Paillassa et al. 2020; Querejeta  
67 et al. 2022; Westerband et al. 2023), and are capable of reconciling dynamic  
68 leaf nitrogen-photosynthesis relationships and acclimation responses to elevated  
69 CO<sub>2</sub>, temperature, light availability, and vapor pressure deficit (Dong et al. 2017;  
70 Dong et al. 2020; Smith and Keenan 2020; Luo et al. 2021; Peng et al. 2021;  
71 Dong et al. 2022; Dong et al. 2022; Querejeta et al. 2022; Westerband et al.

72 2023). Current versions of optimality models that invoke patterns expected from  
73 photosynthetic least-cost theory hold  $\beta$  constant across growing environments.  
74 As growing evidence suggests that costs of nutrient use are plastic across resource  
75 availability and climatic gradients in species with different nutrient acquisition  
76 strategies (Fisher et al. 2010; Brzostek et al. 2014; Terrer et al. 2018; Allen et al.  
77 2020), one might expect that  $\beta$  should dynamically change across environments  
78 and in species with different nutrient acquisition strategies.

79 Patterns expected from photosynthetic least-cost theory have recently been  
80 shown to occur across broad environmental gradients. Despite this, a limited num-  
81 ber of studies have investigated how  $\beta$  varies across edaphic and climatic gradients  
82 and how variance in  $\beta$  might scale to influence leaf nutrient-water use tradeoffs  
83 (Lavergne et al. 2020; Paillassa et al. 2020). Furthermore, no previous study has  
84 investigated whether  $\beta$  varies in species with different nutrient acquisition strate-  
85 gies, or if changes in  $\beta$  due to changes in edaphic characteristics scale to influence  
86 leaf or whole plant acclimation responses to changing environments. The lack of  
87 such studies provided motivation for the experimental chapters included in this  
88 dissertation.

89 In this dissertation, I use a combination of greenhouse, field manipulation,  
90 environmental gradient, and growth chamber experiments to quantify leaf and  
91 whole plant acclimation responses across various climatic and edaphic conditions  
92 and species representing different nutrient acquisition strategies. Together, these  
93 experiments evaluate patterns expected from photosynthetic least-cost theory and  
94 test mechanisms predicted to drive responses expected from theory. The empirical  
95 data collected in these experiments provide important information needed to re-

96 fine existing optimality models that include photosynthetic least-cost frameworks,  
97 and could help determine whether such models are suitable for implementing in  
98 next-generation terrestrial biosphere models. While theory suggests that plants  
99 acclimate across environments by minimizing the summed cost of nutrients relative  
100 to water, I chose to isolate effects of soil nitrogen availability on costs of nitrogen  
101 acquisition relative to water for the sake of brevity. I acknowledge that patterns  
102 expected from theory may be modified by other nutrients (e.g., phosphorus) or  
103 other edaphic characteristics (Smith et al. 2019; Paillassa et al. 2020; Westerband  
104 et al. 2023), and, though not included here, should also be investigated.

105 In the first experimental chapter, I re-analyze data from a greenhouse ex-  
106 periment that grew *Glycine max* and *Gossypium hirsutum* seedlings under full-  
107 factorial combinations of four light treatments and four fertilization treatments  
108 to examine effects of nitrogen and light availability on structural carbon costs to  
109 acquire nitrogen. In the second experimental chapter, I measure leaf physiological  
110 traits in the upper canopy of mature trees growing in a 9-year nitrogen-by-pH  
111 field manipulation experiment to assess whether changes in soil nitrogen availabil-  
112 ity or soil pH modify nitrogen-water use tradeoffs expected from photosynthetic  
113 least-cost theory. In the third experimental chapter, I investigate primary drivers  
114 of leaf nitrogen content across a broad precipitation and soil nitrogen availability  
115 gradient in Texan grasslands. In the fourth experimental chapter, I use growth  
116 chambers to quantify leaf and whole plant acclimation responses to CO<sub>2</sub> in *Glycine*  
117 *max* grown across a soil nitrogen fertilization gradient. I also manipulate nutrient  
118 acquisition strategy by controlling whether *Glycine max* seedlings were able to  
119 form associations with symbiotic nitrogen-fixing bacteria.

120 Across experiments, I find consistent support for patterns expected from  
121 photosynthetic least-cost theory, showing that shifts in edaphic characteristics  
122 predictably alter  $\beta$ , and that  $\beta$  facilitates changes in leaf nitrogen-water use  
123 tradeoffs and leaf nitrogen-photosynthesis relationships. I also show that costs  
124 of nitrogen acquisition vary in species with different nitrogen acquisition strate-  
125 gies. Finally, I show strong evidence suggesting that leaf acclimation responses to  
126 elevated CO<sub>2</sub> are decoupled from soil nitrogen availability and inoculation with  
127 symbiotic nitrogen-fixing bacteria. It is my hope that these experiments will en-  
128 courage future iterations of optimality models that adopt photosynthetic least-cost  
129 frameworks to consider frameworks for implementing dynamic  $\beta$  values across soil  
130 resource availability gradients and in species with different nutrient acquisition  
131 strategies.

132 The four experimental chapters included in this dissertation are presented  
133 either as previously published journal articles or as manuscript drafts currently  
134 in preparation for journal submission. Specifically, the first experimental chapter  
135 was published in *Journal of Experimental Botany* in 2021 and the second chapter  
136 is currently in review, while the third and fourth chapters are each in preparation  
137 for journal submission. The dissertation concludes with a sixth chapter that sum-  
138 marizes experiment findings, briefly synthesizes common themes observed across  
139 experiments, and provides some suggestions for future experimentation.

140

## Chapter 2

141

Structural carbon costs to acquire nitrogen are determined by  
142 nitrogen and light availability in two species with different nitrogen  
143 acquisition strategies

144 Perkowski EA, EF Waring, NG Smith, "Root mass carbon costs to acquire nitro-  
145 gen are determined by nitrogen and light availability in two species with different  
146 nitrogen acquisition strategies", *Journal of Experimental Botany*, 2021, Volume  
147 72, Issue 15, Pages 5766-5776, by permission of Oxford University Press

148 2.1 Introduction

149 Carbon and nitrogen cycles are tightly coupled in terrestrial ecosystems. This  
150 tight coupling influences photosynthesis (Walker et al. 2014; Rogers et al. 2017),  
151 net primary productivity (LeBauer and Treseder 2008; Thomas et al. 2013), de-  
152 composition (Cornwell et al. 2008; Bonan et al. 2013; Sulman et al. 2019), and  
153 plant resource competition (Gill and Finzi 2016; Xu-Ri and Prentice 2017). Ter-  
154 restrial biosphere models are beginning to include connected carbon and nitrogen  
155 cycles to improve the realism of their simulations (Fisher et al. 2010; Brzostek  
156 et al. 2014; Wieder et al. 2015; Shi et al. 2016; Zhu et al. 2019). Simula-  
157 tions from these models indicate that coupling carbon and nitrogen cycles can  
158 drastically influence future biosphere-atmosphere feedbacks under global change,  
159 such as elevated carbon dioxide or nitrogen deposition (Thornton et al. 2007;  
160 Goll et al. 2012; Wieder et al. 2015; Wieder et al. 2019). Nonetheless, there  
161 are still limitations in our quantitative understanding of connected carbon and  
162 nitrogen dynamics (Thomas et al. 2015; Meyerholt et al. 2016; Rogers et al.  
163 2017; Exbrayat et al. 2018; Shi et al. 2019), forcing models to make potentially  
164 unreliable assumptions.

165 Plant nitrogen acquisition is a process in terrestrial ecosystems by which  
166 carbon and nitrogen are tightly coupled (Vitousek and Howarth 1991; Delaire  
167 et al. 2005; Brzostek et al. 2014) [dWS: redundant with above]. Plants must  
168 allocate photosynthetically derived [DWS: as opposed to?] carbon belowground  
169 to produce and maintain root systems or exchange with symbiotic soil microbes in  
170 order to acquire nitrogen (Högberg et al. 2008; Högberg et al. 2010). Thus, plants  
171 have an inherent carbon cost associated with acquiring nitrogen, which can include  
172 both direct energetic costs associated with nitrogen acquisition and indirect costs  
173 associated with building structures that support nitrogen acquisition (Gutschick  
174 1981; Rastetter et al. 2001; Vitousek et al. 2002; Menge et al. 2008). [DWS: You  
175 make this sound more complicated than it is. It is just good old allocation]. Model  
176 simulations (Fisher et al. 2010; Brzostek et al. 2014; Shi et al. 2016; Allen et al.  
177 2020) and meta-analyses (Terrer et al. 2018) suggest that these carbon costs vary  
178 between species, particularly those with different nitrogen acquisition strategies.  
179 For example, simulations using iterations of the Fixation and Uptake of Nitrogen  
180 (FUN) model indicate that species that acquire nitrogen from non-symbiotic active  
181 uptake pathways (e.g. mass flow) generally have larger carbon costs to acquire  
182 nitrogen than species that acquire nitrogen through symbiotic associations with  
183 nitrogen-fixing bacteria (Brzostek et al. 2014; Allen et al. 2020).

184 Carbon costs to acquire nitrogen likely vary in response to changes in soil  
185 nitrogen availability. For example, if the primary mode of nitrogen acquisition  
186 is through non-symbiotic active uptake, then nitrogen availability could decrease  
187 carbon costs to acquire nitrogen as a result of increased per-root nitrogen up-  
188 take (Franklin et al. 2009; Wang et al. 2018). However, if the primary mode of

189 nitrogen acquisition is through symbiotic active uptake, then nitrogen availability  
190 may incur additional carbon costs to acquire nitrogen if it causes microbial  
191 symbionts to shift toward parasitism along the parasitism–mutualism continuum  
192 (Johnson et al. 1997; Hoek et al. 2016; Friel and Friesen 2019) or if it reduces  
193 the nitrogen acquisition capacity of a microbial symbiont (van Diepen et al. 2007;  
194 Soudzilovskaia et al. 2015; Muñoz et al. 2016). Species may respond to shifts in  
195 soil nitrogen availability by switching their primary mode of nitrogen acquisition  
196 to a strategy with lower carbon costs to acquire nitrogen in order to maximize  
197 the magnitude of nitrogen acquired from a belowground carbon investment and  
198 outcompete other individuals for soil resources (Rastetter et al. 2001; Menge et al.  
199 2008).

200 Environmental conditions that affect plant nitrogen demand (e.g., CO<sub>2</sub>,  
201 light availability) could also affect plant carbon costs to acquire nitrogen. For  
202 example, an increase in plant nitrogen demand could increase carbon costs to  
203 acquire nitrogen if this increases the carbon that must be allocated belowground  
204 to acquire a proportional amount of nitrogen (Kulmatiski et al. 2017; Noyce  
205 et al. 2019). This could be driven by a temporary state of diminishing return  
206 associated with investing carbon toward building and maintaining structures that  
207 are necessary to support enhanced nitrogen uptake, such as fine roots (Matamala  
208 and Schlesinger 2000; Norby et al. 2004; Arndal et al. 2018), mycorrhizal hyphae  
209 (Saleh et al. 2020), or root nodules (Parvin et al. 2020). Alternatively, if the  
210 environmental factor that increases plant nitrogen demand causes nitrogen to  
211 become more limiting in the system (e.g. atmospheric CO<sub>2</sub>) (Luo et al. 2004;  
212 LeBauer and Treseder 2008; Vitousek et al. 2010; Liang et al. 2016), species

213 might switch their primary mode of nitrogen acquisition to a strategy with lower  
214 relative carbon costs to acquire nitrogen in order to gain a competitive advantage  
215 over species with either different or more limited modes of nitrogen acquisition  
216 (Ainsworth and Long 2005; Taylor and Menge 2018).

217 Using a plant economics approach, I examined the influence of plant ni-  
218 trogen demand and soil nitrogen availability on plant carbon costs to acquire  
219 nitrogen. This was done by growing a species capable of forming associations  
220 with nitrogen-fixing bacteria (*Glycine max* L. (Merr)) and a species not capable  
221 of forming these associations (*Gossypium hirsutum* L.) under four levels of light  
222 availability (plant nitrogen demand proxy) and four levels of soil nitrogen fertil-  
223 ization (soil nitrogen availability proxy) in a full-factorial, controlled greenhouse  
224 experiment. [DWS: these species come out of nowhere? Why these two? Seems  
225 random. I mean they are both rosids but otherwise? What can one learn by just  
226 growing two random species out of hundreds of thousands? You need to justify  
227 this or it is a huge surprise..]

228 I used this experimental set-up to test the following hypotheses:

- 229 1. An increase in plant nitrogen demand due to increasing light availability will  
230 increase carbon costs to acquire nitrogen through a proportionally larger  
231 increase in belowground carbon than whole-plant nitrogen acquisition. This  
232 will be the result of an increased investment of carbon toward belowground  
233 structures that support enhanced nitrogen uptake, but at a lower nitrogen  
234 return.
- 235 2. An increase in soil nitrogen availability will decrease carbon costs to acquire

236 nitrogen as a result of increased per root nitrogen uptake in *G. hirsutum*.  
237 However, soil nitrogen availability will not affect carbon costs to acquire  
238 nitrogen in *G. max* because of the already high return of nitrogen supplied  
239 through nitrogen fixation.

240 2.2 Methods

241 2.2.1 *Experiment setup*

242 *Gossypium hirsutum* and *G. max*. were planted in individual 3 liter pots (NS-300;  
243 Nursery Supplies, Orange, CA, USA) containing a 3:1 mix of unfertilized potting  
244 mix (Sungro Sunshine Mix #2, Agawam, MA, USA) to native soil extracted from  
245 an agricultural field most recently planted with *G. max* at the USDA-ARS Lab-  
246 oratory in Lubbock, TX, USA ( $33.59^{\circ}\text{N}$ ,  $-101.90^{\circ}\text{W}$ ). The field soil was classified  
247 as Amarillo fine sandy loam (75% sand, 10% silt, 15% clay). Upon planting,  
248 all *G. max* pots were inoculated with *Bradyrhizobium japonicum* (Verdesian N-  
249 Dure<sup>TM</sup> Soybean, Cary, NC, USA) to stimulate root nodulation. Individuals of  
250 both species were grown under similar, unshaded, ambient greenhouse conditions  
251 for 2 weeks to germinate and begin vegetative growth.

252 Three blocks were set up in the greenhouse, each containing four light  
253 treatments created using shade cloth that reduced incoming radiation by either 0  
254 (full sun), 30, 50, or 80%. Two weeks post-germination, individuals were randomly  
255 placed in the four light treatments in each block. Individuals received one of four  
256 nitrogen fertilization doses as 100mL of a modified Hoagland solution (Hoagland  
257 and Arnon 1950) equivalent to either 0, 70, 210, or 630 ppm N twice per week  
258 within each light treatment. Nitrogen fertilization doses were received as topical

259 agents to the soil surface. Each Hoagland solution was modified to keep concen-  
260 trations of other macro- and micronutrients equivalent (Table A1). Plants were  
261 routinely well watered to eliminate water stress.

262 2.2.2 *Plant measurements and calculations*

263 Each individual was harvested after 5 weeks of treatment, and biomass was sepa-  
264 rated by organ type (leaves, stems, and roots). Nodules on *G. max* roots were also  
265 harvested. Except for the 0% shade cover and 630 ppm N treatment combination,  
266 all treatment combinations in both species had lower average dry biomass:pot vol-  
267 ume ratios than the 1:1 ratio recommended by Poorter et al. (2012) to minimize  
268 the likelihood of pot volume-induced growth limitation (Table A2, A3; Fig. A1).

269 All harvested material was dried, weighed, and ground by organ type.  
270 Carbon and nitrogen content ( $\text{g g}^{-1}$ ) was determined by subsampling from ground  
271 and homogenized biomass of each organ type using an elemental analyzer (Costech  
272 4010; Costech, Inc., Valencia, CA, USA). I scaled these values to total leaf, stem,  
273 and root carbon and nitrogen biomass (g) by multiplying dry biomass of each  
274 organ type by carbon or nitrogen content of each corresponding organ type. Whole  
275 plant nitrogen biomass (g) was calculated as the sum of total leaf (g), stem (g),  
276 and root (g) nitrogen biomass. Root nodule carbon biomass was not included in  
277 the calculation of root carbon biomass; however, relative plant investment toward  
278 root or root nodule standing stock was estimated as the ratio of root biomass to  
279 root nodule biomass ( $\text{g g}^{-1}$ ), following similar metrics to those adopted by Dovrat  
280 et al. (2018) and Dovrat et al. (2020).

281 Carbon costs to acquire nitrogen ( $N_{\text{cost}}$ ;  $\text{gC gN}^{-1}$ ) were estimated as the

282 ratio of total root carbon biomass ( $C_{bg}$ ; gC) to whole-plant nitrogen biomass  
283 ( $N_{wp}$ ; gN). This calculation quantifies the relationship between carbon spent on  
284 nitrogen acquisition and whole plant nitrogen acquisition by using root carbon  
285 biomass as a proxy for estimating the magnitude of carbon allocated toward ni-  
286 trogen acquisition. This calculation therefore assumes that the magnitude of root  
287 carbon standing stock is proportional to carbon transferred to root nodules or my-  
288 corrhizae, or lost through root exudation or turnover. The assumption has been  
289 supported in species that associate with ectomycorrhizal fungi (Hobbie 2006; Hob-  
290 bie and Hobbie 2008), but is less clear in species that acquire nitrogen through  
291 non-symbiotic active uptake or symbiotic nitrogen fixation. It is also unclear  
292 whether relationships between root carbon standing stock and carbon transfer to  
293 root nodules are similar in magnitude to carbon lost through exudation or when  
294 allocated toward other active uptake pathways. Thus, because of the way mea-  
295 surements were calculated, proximal values of carbon costs to acquire nitrogen are  
296 underestimates.

297 2.2.3 *Statistical analyses*

298 I explored the effects of light and nitrogen availability on carbon costs to acquire  
299 nitrogen using separate linear mixed-effects models for each species. Models in-  
300 cluded shade cover, nitrogen fertilization, and interactions between shade cover  
301 and nitrogen fertilization as continuous fixed effects, and also included block as a  
302 random intercept term. Three separate models for each species were built with  
303 this independent variable structure for three different dependent variables: (i)  
304 carbon costs to acquire nitrogen (gC gN<sup>-1</sup>); (ii) whole plant nitrogen biomass

305 (denominator of carbon cost to acquire nitrogen; gN); and (iii) belowground car-  
306 bon biomass (numerator of carbon cost to acquire nitrogen; gC). I constructed two  
307 additional models for *G. max* with the same model structure described above to  
308 investigate the effects of light availability and nitrogen fertilization on root nodule  
309 biomass (g) and the ratio of root nodule biomass to root biomass (unitless).

310 I used Shapiro–Wilk tests of normality to determine whether species spe-  
311 cific linear mixed-effects model residuals followed a normal distribution. Zero  
312 models satisfied residual normality assumptions when models were fit using un-  
313 transformed data (Shapiro–Wilk:  $p<0.05$  in all cases). I attempted to satisfy  
314 residual normality assumptions by first fitting models using dependent variables  
315 that were natural-log transformed. If residual normality assumptions were still  
316 not met (Shapiro–Wilk:  $p<0.05$ ), then models were fit using dependent variables  
317 that were square root transformed. All residual normality assumptions were satis-  
318 fied when models were fit with either a natural-log or square root transformation  
319 (Shapiro–Wilk:  $p>0.05$  in all cases). Specifically, I natural-log transformed *G.*  
320 *hirsutum* carbon costs to acquire nitrogen and *G. hirsutum* whole-plant nitrogen  
321 biomass. I also square root transformed *G. max* carbon costs to acquire nitrogen,  
322 *G. max* whole-plant nitrogen biomass, root carbon biomass in both species, *G.*  
323 *max* root nodule biomass, and the *G. max* ratio of root nodule biomass to root  
324 biomass. I used the ‘lmer’ function in the ‘lme4’ R package (Bates et al. 2015) to  
325 fit each model and the ‘Anova’ function in the ‘car’ R package (Fox and Weisberg  
326 2019) to calculate Wald’s  $\chi^2$  to determine the significance ( $\alpha=0.05$ ) of each fixed  
327 effect coefficient. Finally, I used the ‘emmeans’ R package (Lenth 2019) to conduct  
328 post-hoc comparisons of our treatment combinations using Tukey’s tests. Degrees

**329** of freedom for all Tukey's tests were approximated using the Kenward–Roger ap-  
**330** proach (Kenward and Roger 1997). All analyses and plots were conducted in R  
**331** version 4.0.1 (R Core Team 2021).

**332** 2.3 Results

**333** 2.3.1 *Carbon costs to acquire nitrogen*

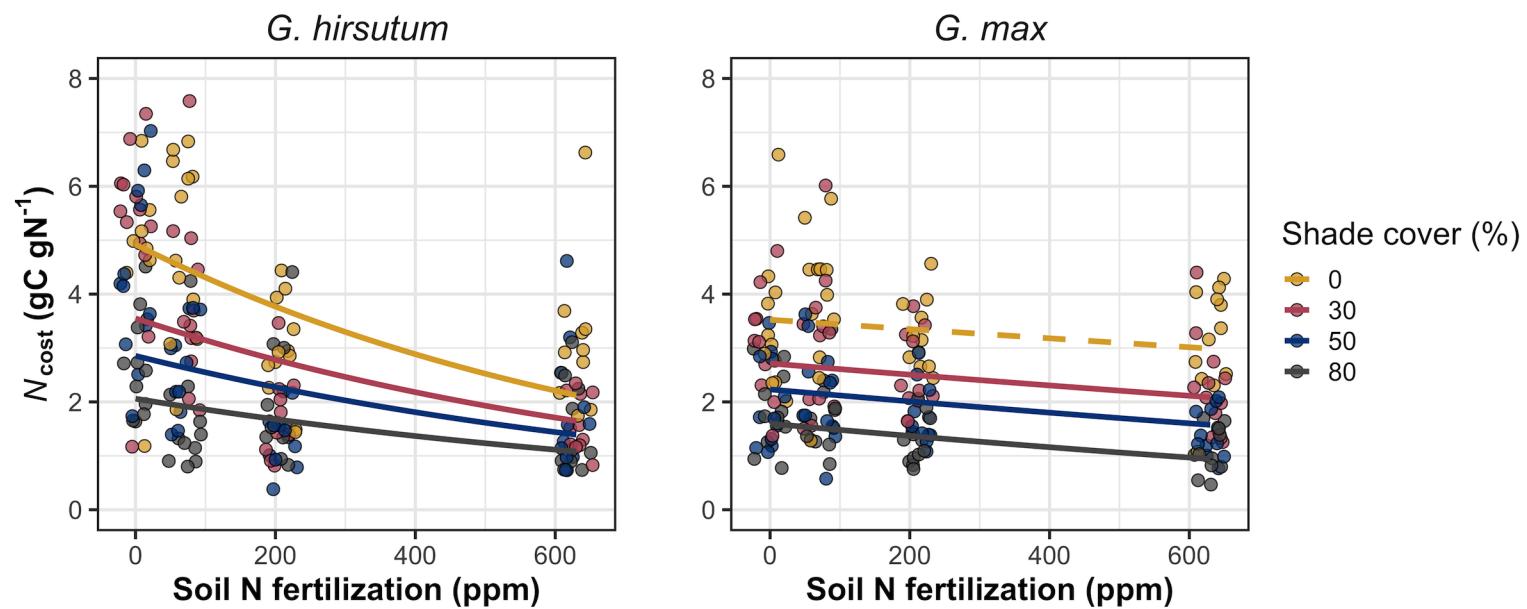

**334** Carbon costs to acquire nitrogen in *G. hirsutum* increased with increasing light  
**335** availability ( $p<0.001$ ; Table 2.1; Fig. 2.1) and decreased with increasing nitrogen  
**336** fertilization ( $p<0.001$ ; Table 2.1; Fig. 2.1). There was no interaction between  
**337** light availability and nitrogen fertilization ( $p=0.486$ , Table 2.1; Fig. 2.1).

**338** Carbon costs to acquire nitrogen in *G. max* also increased with increasing  
**339** light availability ( $p<0.001$ , Table 2.1; Fig. 2.1) and decreased with increasing  
**340** nitrogen fertilization ( $p<0.001$ ; Table 2.1; Fig. 2.1). There was no interaction  
**341** between light availability and nitrogen fertilization ( $p=0.261$ , Table 2.1; Fig. 2.1).

**Table 2.1.** Analysis of variance results exploring species-specific effects of light availability, nitrogen fertilization, and their interactions on carbon costs to acquire nitrogen ( $N_{\text{cost}}$ ; gC gN $^{-1}$ ), whole plant nitrogen biomass ( $N_{\text{wp}}$ ; gN), and root carbon biomass ( $C_{\text{bg}}$ ; gC)

342 \*Significance determined using Wald's  $\chi^2$  tests ( $p=0.05$ ).  $P$ -values less than 0.05 are in bold and  $p$ -values between  
 343 0.05 and 0.1 are italicized. Negative coefficients for light treatments indicate a positive effect of increasing light  
 344 availability on all response variables, as light availability is treated as percent shade cover in all linear mixed-effects  
 345 models.

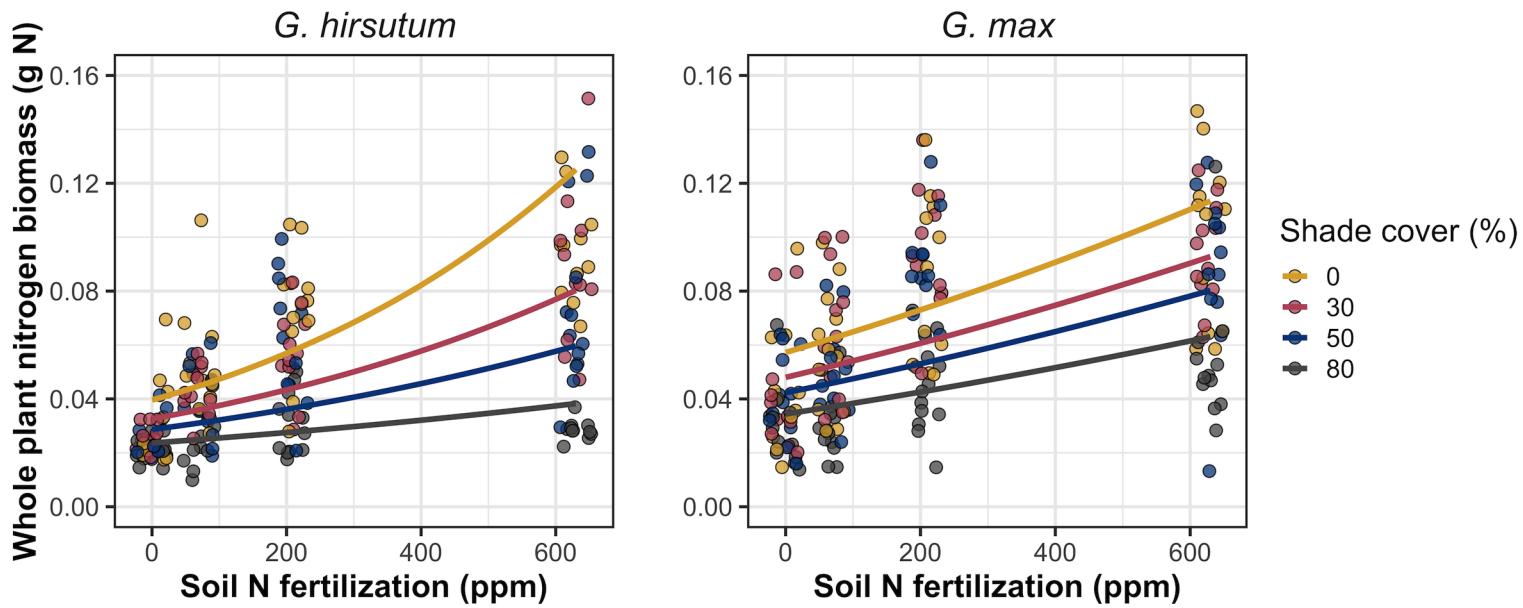

**Figure 2.1.** Relationships between soil nutrient fertilization and light availability on carbon costs to acquire nitrogen in *G. hirsutum* and *G. max*. Nitrogen fertilization treatments are represented on the x-axis. Shade cover treatments are represented through colored points and trendlines. Trendlines were created by back-transforming marginal mean slopes and intercepts from species-specific linear mixed-effects models. These values were calculated using the ‘emtrends’ and ‘emmeans’ functions in the ‘emmeans’ R package (Lenth 2019). Yellow points and trendlines represent the 0% shade cover treatment, red points and trendlines represent the 30% shade cover treatment, blue points and trendlines represent the 50% shade cover treatment, and gray points and trendlines represent the 80% shade cover treatment. Solid trendlines indicate slopes that are significantly different from zero (Tukey:  $p < 0.05$ ), while dashed trendlines indicate slopes that are not statistically different from zero.

**346** 2.3.2 *Whole plant nitrogen biomass*

**347** Whole plant nitrogen biomass in *G. hirsutum* was driven by an interaction between  
**348** light availability and nitrogen fertilization ( $p=0.001$ ; Table 2.1; Fig. 2.2). This  
**349** interaction indicated a greater stimulation of whole-plant nitrogen biomass by  
**350** nitrogen fertilization as light levels increased (Table 2.1; Fig. 2.2).

**351** Whole plant nitrogen biomass in *G. max* increased with increasing light  
**352** availability ( $p<0.001$ ) and nitrogen fertilization ( $p<0.001$ ), with no interaction  
**353** between light availability and nitrogen fertilization ( $p=0.231$ ; Table 2.1; Fig. 2.2).

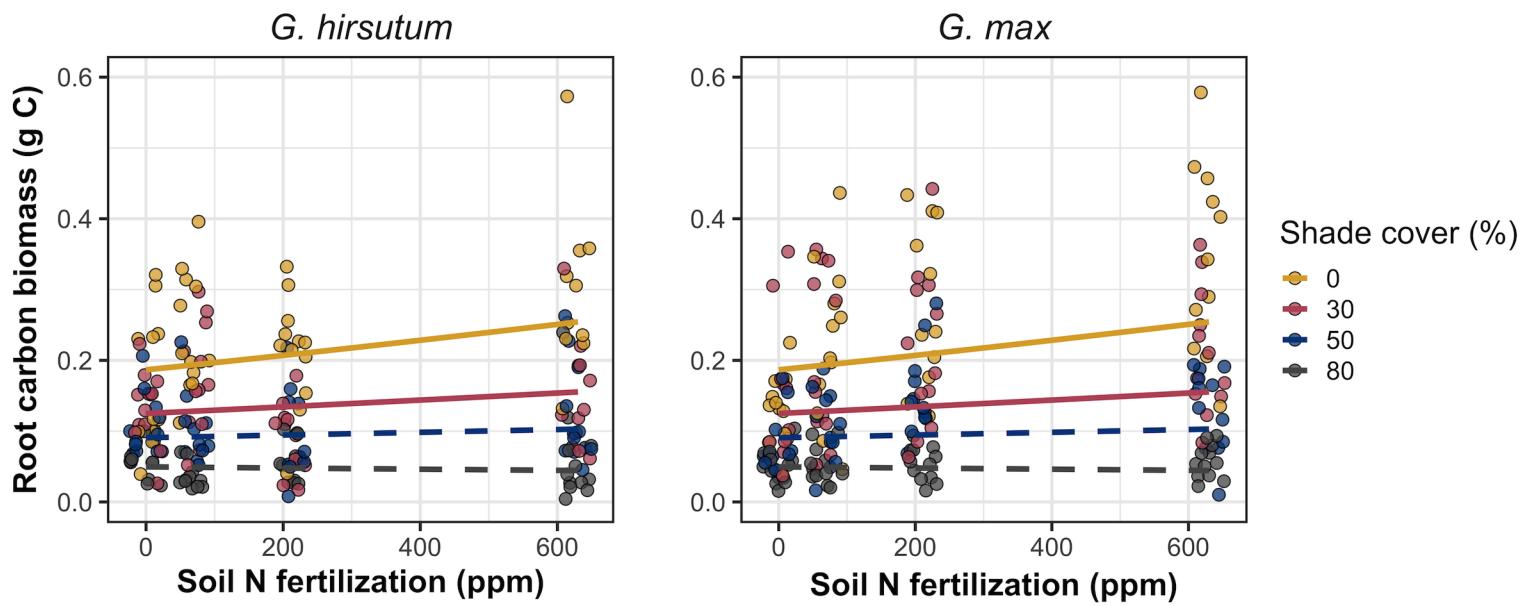

**Figure 2.2.** Relationships between soil nutrient fertilization and light availability on whole-plant nitrogen biomass in *G. hirsutum* and *G. max*. Whole-plant nitrogen biomass is the denominator of the carbon cost to acquire nitrogen calculation. Nitrogen fertilization treatments are represented on the x-axis. Shade cover treatments are represented through colored points and trendlines. Trendlines were created by back-transforming marginal mean slopes and intercepts from species-specific linear mixed-effects models. These values were calculated using the ‘emtrends’ and ‘emmeans’ functions in the ‘emmeans’ R package (Lenth 2019). Points are jittered for visibility. Colored points and trendlines are as explained in Fig. 2.1. Solid trendlines indicate slopes that are significantly different from zero (Tukey:  $p < 0.05$ ), while dashed trendlines indicate slopes that are not statistically different from zero.

**354** 2.3.3 *Root carbon biomass*

**355** Root carbon biomass in *G. hirsutum* significantly increased with increasing light availability ( $p<0.001$ ; Table 2.1; Fig. 2.3) and marginally increased with nitrogen fertilization ( $p=0.089$ ; Table 2.1; Fig. 2.3). There was also a marginal interaction between light availability and nitrogen fertilization ( $p=0.076$ ; Table 2.1), driven by an increase in the positive response of root carbon biomass to increasing nitrogen fertilization as light availability increased (Table 2.3). This pattern resulted in significantly positive trends between root carbon biomass and nitrogen fertilization in the two highest light treatments (Tukey:  $p<0.05$  in both cases; Table 2.3; Fig. 2.3) and no effect of nitrogen fertilization in the two lowest light treatments (Tukey:  $p>0.05$  in both cases; Table 2.3; Fig. 2.3).

**365** There was an interaction between light availability and nitrogen fertilization on root carbon biomass in *G. max* ( $p=0.001$ ; Table 2.1; Fig. 2.3). Post-hoc analyses indicated that the positive effects of nitrogen fertilization on *G. max* root carbon biomass increased with increasing light availability (Table 2.3; Fig. 2.3). There were also positive individual effects of increasing nitrogen fertilization ( $p<0.001$ ; Table 2.3) and light availability ( $p<0.001$ ; Table 2.3) on *G. max* root carbon biomass (Table 2.1; Fig. 2.3).

**Figure 2.3.** Relationships between soil nutrient fertilization and light availability on root carbon biomass in *G. hirsutum* and *G. max*. Root carbon biomass is the numerator of the carbon cost to acquire nitrogen calculation. Nitrogen fertilization treatments are represented on the x-axis. Colored points and trendlines are as explained in Fig. 2.1. Trendlines were created by back-transforming marginal mean slopes and intercepts from species-specific linear mixed-effects models. These values were calculated using the ‘emtrends’ and ‘emmeans’ functions in the ‘emmeans’ R package (Lenth 2019). Points are jittered for visibility. Colored points and trendlines are as explained in Fig. 2.1.

**372** 2.3.4 *Root nodule biomass*

**373** Root nodule biomass in *G. max* increased with increasing light availability ( $p <$   
**374** 0.001; Table 2.2; Fig. 2.4a) and decreased with increasing nitrogen fertilization  
**375** ( $p < 0.001$ ; Table 2.2; Fig. 2.4a). There was no interaction between nitrogen  
**376** fertilization and light availability ( $p = 0.133$ ; Table 2.2; Fig. 2.4a). The ratio of  
**377** root nodule biomass to root biomass did not change in response to light availability  
**378** ( $p = 0.481$ ; Table 2.2; Fig. 2.4b) but decreased with increasing nitrogen fertilization  
**379** ( $p < 0.001$ ; Table 2.2; Fig. 2.4b). There was no interaction between nitrogen  
**380** fertilization and light availability on the ratio of root nodule biomass to root  
**381** biomass ( $p = 0.621$ ; Table 2.2; Fig. 2.4b).

**Table 2.2.** Analysis of variance results exploring effects of light availability, nitrogen fertilization, and their interactions on *G. max* root nodule biomass (g) and the ratio of root nodule biomass to root biomass (g g<sup>-1</sup>)\*

	Nodule biomass			Nodule biomass: root biomass			
	df	Coefficient	$\chi^2$	p	Coefficient	$\chi^2$	p
(Intercept)		$3.02 * 10^{-1}$	-	-	$4.48 * 10^{-1}$	-	-
Light (L)	1	$-1.81 * 10^{-3}$	72.964	<b>&lt;0.001</b>	$-8.76 * 10^{-5}$	0.496	0.481
Nitrogen (N)	1	$-2.83 * 10^{-4}$	115.377	<b>&lt;0.001</b>	$-5.09 * 10^{-4}$	156.476	<b>&lt;0.001</b>
L*N	1	$1.14 * 10^{-6}$	2.226	0.133	$-7.30 * 10^{-7}$	0.244	0.621

382 \*Significance determined using Wald's  $\chi^2$  tests ( $\alpha=0.05$ ). P-values less than 0.05 are in bold. Negative coefficients for  
 383 light treatments indicate a positive effect of increasing light availability on all response variables, as light availability  
 384 is treated as percent shade cover in all linear mixed-effects models. Root nodule biomass and nodule biomass: root  
 385 biomass models were only constructed for *G. max* because *G. hirsutum* was not inoculated with *B. japonicum* and  
 386 is not capable of forming root nodules.

**Table 2.3.** Slopes of the regression line describing the relationship between each dependent variable and nitrogen fertilization at each light level\*

387 \* Slopes represent estimated marginal mean slopes from linear mixed-effects models described in the Methods. Slopes  
 388 were calculated using the ‘emmeans’ R package (Lenth 2019). Superscripts indicate slopes fit to natural-log (<sup>a</sup>) or  
 389 square root (<sup>b</sup>) transformed data. Slopes statistically different from zero (Tukey:  $p < 0.05$ ) are indicated in bold.  
 390 Marginally significant slopes (Tukey:  $0.05 < p < 0.1$ ) are italicized.

**Figure 2.4.** Effects of shade cover and nitrogen fertilization on root nodule biomass (a) and the ratio of root nodule biomass to root biomass (b) in *G. max*. Nitrogen fertilization treatments are represented on the x-axis. Shade cover treatments are represented through colored points and trendlines. Trendlines were created by back-transforming marginal mean slopes and intercepts from species-specific linear mixed-effects models. These values were calculated using the ‘emtrends’ and ‘emmeans’ functions in the ‘emmeans’ R package (Lenth 2019). Points are jittered for visibility. Yellow points and trendlines represent the 0% shade cover treatment, blue points and trendlines represent the 30% shade cover treatment, green points and trendlines represent the 50% shade cover treatment, and purple points and trendlines represent the 80% shade cover treatment. Solid trendlines indicate slopes that are significantly different from zero (Tukey:  $p < 0.05$ ), while dashed trendlines indicate slopes that are not statistically different from zero.

**391** 2.4 Discussion

**392** In this chapter, I determined the effects of light availability and soil nitrogen  
**393** fertilization on root mass carbon costs to acquire nitrogen in *G. hirsutum* and *G.*  
**394** *max*. In support of my hypotheses, I found that carbon costs to acquire nitrogen  
**395** generally increased with increasing light availability and decreased with increasing  
**396** soil nitrogen fertilization in both species. These findings suggest that carbon costs  
**397** to acquire nitrogen are determined by factors that influence plant nitrogen demand  
**398** and soil nitrogen availability. In contrast to my second hypothesis, root nodulation  
**399** data suggested that *G. max* and *G. hirsutum* achieved similar directional carbon  
**400** cost responses to nitrogen fertilization despite a likely shift in *G. max* allocation  
**401** from nodulation to root biomass along the nitrogen fertilization gradient.

**402** 2.4.1 *Carbon costs to acquire nitrogen increase with light availability and*  
**403** *decrease with fertilization*

**404** Both *G. max* and *G. hirsutum* experienced an increase in carbon costs to ac-  
**405** quire nitrogen due to increasing light availability. These patterns were driven by  
**406** a larger increase in root carbon biomass than whole-plant nitrogen biomass. In-  
**407** creases in root carbon biomass due to factors that increase plant nitrogen demand  
**408** are a commonly observed pattern, as carbon allocated belowground provides sub-  
**409** strate needed to produce and maintain structures that satisfy aboveground plant  
**410** nitrogen demand (Nadelhoffer and Raich 1992; Giardina et al. 2005; Raich et al.  
**411** 2014). Findings suggest that plants allocate relatively more carbon for acquiring  
**412** nitrogen when demand increases over short temporal scales, which may cause a  
**413** temporary state of diminishing return due to asynchrony between belowground

414 carbon and whole-plant nitrogen responses to plant nitrogen demand (Kulmatiski  
415 et al. 2017; Noyce et al. 2019). These responses might be attributed to a temporal  
416 lag associated with producing structures that enhance nitrogen acquisition. For  
417 example, fine roots (Matamala and Schlesinger 2000; Norby et al. 2004; Arndal  
418 et al. 2018) and root nodules (Parvin et al. 2020) take time to build and first  
419 require the construction of coarse roots. Thus, full nitrogen returns from these  
420 investments may not occur immediately (Kayler et al. 2010; Kayler et al. 2017),  
421 and may vary by species acquisition strategy. I speculate that increases in ni-  
422 trogen acquisition from a given carbon investment may occur beyond the 5-week  
423 scope of this experiment. A similar study conducted over a longer temporal scale  
424 would address this.

425 Increasing soil nitrogen fertilization generally decreased carbon costs to  
426 acquire nitrogen in both species. These patterns were driven by a larger increase  
427 in whole-plant nitrogen biomass than root carbon biomass. In *G. hirsutum*, re-  
428 ductions in carbon costs to acquire nitrogen may have been due to an increase in  
429 per-root nitrogen uptake, allowing individuals to maximize the amount of nitro-  
430 gen acquired from a belowground carbon investment. Interestingly, increased soil  
431 nitrogen fertilization increased whole-plant nitrogen biomass in *G. max* despite  
432 reductions in root nodule biomass that likely reduced the nitrogen-fixing capac-  
433 ity of *G. max* (Andersen et al. 2005; Muñoz et al. 2016). While reductions in  
434 root nodulation due to increased soil nitrogen availability are commonly observed  
435 (Gibson and Harper 1985; Fujikake et al. 2003), root nodulation responses were  
436 observed in tandem with increased root carbon biomass, implying that *G. max*  
437 shifted relative carbon allocation from nitrogen fixation to soil nitrogen acquisition

438 (Markham and Zekveld 2007; Dovrat et al. 2020). This was likely because there  
439 was a reduction in the carbon cost advantage of acquiring fixed nitrogen relative  
440 to soil nitrogen, and suggests that species capable of associating with symbiotic  
441 nitrogen-fixing bacteria shift their relative nitrogen acquisition pathway to opti-  
442 mize nitrogen uptake (Rastetter et al. 2001). Future studies should investigate  
443 these patterns with a larger quantity of phylogenetically related species, or differ-  
444 ent varieties of a single species that differ in their ability to form associations with  
445 symbiotic nitrogen-fixing bacteria to more directly test the impact of nitrogen  
446 fixation on the patterns observed in this study.

447 2.4.2 *Modeling implications*

448 Carbon costs to acquire nitrogen are subsumed in the general discussion of eco-  
449 nomic analogies to plant resource uptake (Bloom et al. 1985; Rastetter et al.  
450 2001; Vitousek et al. 2002; Phillips et al. 2013; Terrer et al. 2018; Henneron et al.  
451 2020). Despite this, terrestrial biosphere models rarely include costs of nitrogen  
452 acquisition to predict plant nitrogen uptake. There is currently one plant resource  
453 uptake model, the Fixation and Uptake of Nitrogen model (FUN), that quantita-  
454 tively predicts carbon costs to acquire nitrogen within a framework for predicting  
455 plant nitrogen uptake for different nitrogen acquisition strategies (Fisher et al.  
456 2010; Brzostek et al. 2014). Iterations of FUN are currently coupled to two ter-  
457 restrial biosphere models: the Community Land Model 5.0 and the Joint UK Land  
458 Environment Simulator (Clark et al. 2011; Shi et al. 2016; Lawrence et al. 2019).  
459 Recent work suggests that coupling FUN to CLM 5.0 caused a large overpredic-  
460 tion of plant nitrogen uptake associated with nitrogen fixation (Davies-Barnard

461 et al. 2020) compared to other terrestrial biosphere model products. Thus, em-  
462 pirical data from manipulative experiments that explicitly quantify carbon costs  
463 to acquire nitrogen in species capable of associating with nitrogen-fixing bacteria  
464 across different environmental contexts is an important step toward identifying  
465 potential biases in models such as FUN.

466 These findings support the FUN formulation of carbon costs to acquire  
467 nitrogen in response to soil nitrogen availability. FUN calculates carbon costs  
468 to acquire nitrogen based on the sum of carbon costs to acquire nitrogen via ni-  
469 trogen fixation, mycorrhizal active uptake, non-mycorrhizal active uptake, and  
470 retranslocation (Fisher et al. 2010; Brzostek et al. 2014). Carbon costs to acquire  
471 nitrogen via mycorrhizal or non-mycorrhizal active uptake pathways are derived  
472 as a function of nitrogen availability, root biomass, and two parameterized values  
473 based on nitrogen acquisition strategy (Brzostek et al. 2014). Due to this, FUN  
474 simulates a net decrease in carbon costs to acquire nitrogen with increasing ni-  
475 trogen availability for mycorrhizal and non-mycorrhizal active uptake pathways,  
476 assuming constant root biomass. This was a pattern I observed in *G. hirsutum* re-  
477 gardless of light availability. In contrast, FUN would not simulate a net change in  
478 carbon costs to acquire nitrogen via nitrogen fixation due to nitrogen availability.  
479 This is because carbon costs to acquire nitrogen via nitrogen fixation are derived  
480 from a well established function of soil temperature, which is independent of soil  
481 nitrogen availability (Houlton et al. 2008; Fisher et al. 2010). I observed a net  
482 reduction in carbon costs to acquire nitrogen in *G. max*, except when individu-  
483 als were grown under 0% shade cover. While a net reduction of carbon costs in  
484 response to nitrogen fertilization runs counter to nitrogen fixation carbon costs

485 simulated by FUN, these patterns were likely because *G. max* individuals switched  
486 their primary mode of nitrogen acquisition from symbiotic nitrogen fixation to a  
487 non-symbiotic active uptake pathway.

488 2.4.3 *Study limitations*

489 The metric used in this study to determine carbon costs to acquire nitrogen has  
490 several limitations. Most notably, this metric uses root carbon biomass as a proxy  
491 for estimating the amount of carbon spent on nitrogen acquisition. Although it is  
492 true that most carbon allocated belowground has at least an indirect structural  
493 role in acquiring soil resources, it remains unclear whether this assumption holds  
494 true for species that acquire nitrogen via symbiotic nitrogen fixation. I also cannot  
495 quantify carbon lost through root exudates or root turnover, which may increase  
496 due to factors that increase plant nitrogen demand (Tingey et al. 2000; Phillips  
497 et al. 2011), and can increase the magnitude of available nitrogen from soil organic  
498 matter through priming effects on soil microbial communities (Uselman et al.  
499 2000; Bengtson et al. 2012). It is also not clear whether these assumptions  
500 hold under all environmental conditions, such as those that shift belowground  
501 carbon allocation toward a different mode of nitrogen acquisition (Taylor and  
502 Menge 2018; Friel and Friesen 2019) or between species with different acquisition  
503 strategies. In this study, increasing soil nitrogen fertilization increased carbon  
504 investment to roots relative to carbon transferred to root nodules. By assuming  
505 that carbon allocated to root carbon was proportional to carbon allocated to  
506 root nodules across all treatment combinations, these observed responses to soil  
507 nitrogen fertilization were likely to be overestimated in *G. max*. I encourage future

508 research to quantify these carbon fates independently.

509 [DWS: also you looked at two species out of hundreds of thousands of  
510 possible species! It is anecdotal]

511 Researchers conducting pot experiments must carefully choose pot volume  
512 to minimize the likelihood of growth limitations induced by pot volume (Poorter  
513 et al. 2012). Poorter et al. (2012) indicate that researchers are likely to avoid  
514 growth limitations associated with pot volume if measurements are collected when  
515 the plant biomass:pot volume ratio is less than  $1 \text{ g L}^{-1}$ . In this experiment, all  
516 treatment combinations in both species had biomass:pot volume ratios less than  
517  $1 \text{ g L}^{-1}$  except for *G. max* and *G. hirsutum* that were grown under 0% shade  
518 cover and had received 630 ppm N. Specifically, *G. max* and *G. hirsutum* had  
519 average respective biomass:pot volume ratios of  $1.24 \pm 0.07 \text{ g L}^{-1}$  and  $1.34 \pm 0.13$   
520  $\text{g L}^{-1}$ , when grown under 0% shade cover and received 630 ppm N (Table A2,  
521 A3; Fig. A1). If growth in this treatment combination was limited by pot vol-  
522 ume, then individuals may have had larger carbon costs to acquire nitrogen than  
523 would be expected if they were grown in larger pots. This pot volume induced  
524 growth limitation could cause a reduction in per-root nitrogen uptake associated  
525 with more densely packed roots, which could reduce the positive effect of nitro-  
526 gen fertilization on whole-plant nitrogen biomass relative to root carbon biomass  
527 (Poorter et al. 2012).

528 Pot size may have limited plant growth, which provides a possible expla-  
529 nation for the marginally insignificant effect of increasing nitrogen fertilization on  
530 *G. max* carbon costs to acquire nitrogen when grown under 0% shade cover. This  
531 is because the regression line describing the relationship between carbon costs to

532 acquire nitrogen and nitrogen fertilization in *G. max* grown under 0% shade cover  
533 would have flattened if growth limitation had caused larger than expected carbon  
534 costs to acquire nitrogen in the 0% shade cover, 630 ppm N treatment combi-  
535 nation. This may have been exacerbated by the fact that *G. max* likely shifted  
536 relative carbon allocation from nitrogen fixation to soil nitrogen acquisition, which  
537 could have increased the negative effect of more densely packed roots on nitrogen  
538 uptake. These patterns could have also occurred in *G. hirsutum* grown under 0%  
539 shade cover; however, there was no change in the effect of nitrogen fertilization on  
540 *G. hirsutum* carbon costs to acquire nitrogen grown under 0% shade cover relative  
541 to other shade cover treatments. Regardless, the possibility of growth limitation  
542 due to pot volume suggests that effects of increasing nitrogen fertilization on car-  
543 bon costs to acquire nitrogen in both species grown under 0% shade cover could  
544 have been underestimated. Follow-up studies using a similar experimental design  
545 with a larger pot volume would be necessary in order to determine whether these  
546 patterns were impacted by pot volume-induced growth limitation.

547 2.4.4 *Conclusions*

548 In conclusion, this chapter provides empirical evidence that carbon costs to ac-  
549 quire nitrogen are influenced by light availability and soil nitrogen fertilization  
550 in a species capable of acquiring nitrogen via symbiotic nitrogen fixation and a  
551 species not capable of forming such associations. We show that carbon costs to  
552 acquire nitrogen generally increase with increasing light availability and decrease  
553 with increasing nitrogen fertilization. This chapter provides important empirical  
554 data needed to evaluate the formulation of carbon costs to acquire nitrogen in

555 terrestrial biosphere models, particularly carbon costs to acquire nitrogen that  
556 are associated with symbiotic nitrogen fixation. Findings broadly support the  
557 general formulation of these carbon costs in the FUN biogeochemical model in  
558 response to shifts in nitrogen availability. However, there is a need for future  
559 studies to explicitly quantify carbon costs to acquire nitrogen under different en-  
560 vironmental contexts, over longer temporal scales, and using larger selections of  
561 phylogenetically related species. In addition, I suggest that future studies mini-  
562 mize the limitations associated with the metric used here by explicitly measuring  
563 belowground carbon fates independently.

564

## Chapter 3

565 Soil nitrogen availability modifies leaf nitrogen economies in mature  
566 temperate deciduous forests: a direct test of photosynthetic least-cost  
567 theory

568 3.1 Introduction

569 Photosynthesis represents the largest carbon flux between the atmosphere and  
570 land surface (IPCC 2021), and plays a central role in biogeochemical cycling at  
571 multiple spatial and temporal scales (Vitousek and Howarth 1991; LeBauer and  
572 Treseder 2008; Kaiser et al. 2015; Wieder et al. 2015). Therefore, carbon and  
573 energy fluxes simulated by terrestrial biosphere models are sensitive to the formu-  
574 lation of photosynthetic processes (Ziehn et al. 2011; Bonan et al. 2011; Booth  
575 et al. 2012; Smith et al. 2016; Smith et al. 2017) and must be represented using  
576 robust, empirically tested processes (Prentice et al. 2015; Wieder et al. 2019).  
577 Current formulations of photosynthesis vary across terrestrial biosphere models  
578 (Smith and Dukes 2013; Rogers et al. 2017), which causes variation in modeled  
579 ecosystem processes (Knorr 2000; Knorr and Heimann 2001; Bonan et al. 2011;  
580 Friedlingstein et al. 2014) and casts uncertainty on the ability of these models to  
581 accurately predict terrestrial ecosystem responses and feedbacks to global change  
582 (Zaehle et al. 2005; Schaefer et al. 2012; Davies-Barnard et al. 2020).

583 Terrestrial biosphere models commonly represent C<sub>3</sub> photosynthesis through  
584 variants of the Farquhar et al. (1980) biochemical model (Smith and Dukes 2013;  
585 Rogers 2014; Rogers et al. 2017). This well-tested photosynthesis model estimates  
586 leaf-level carbon assimilation, or photosynthetic capacity, as a function of the  
587 maximum rate of Ribulose-1,5-bisphosphate carboxylase-oxygenase (Rubisco) car-

588 boxylation ( $V_{cmax}$ ) and the maximum rate of Ribulose-1,5-bisphosphate (RuBP)  
589 regeneration ( $J_{max}$ ) (Farquhar et al. 1980). Many terrestrial biosphere models  
590 predict these model inputs based on plant functional group specific linear rela-  
591 tionships between leaf nutrient content and  $V_{cmax}$  (Smith and Dukes 2013; Rogers  
592 2014; Rogers et al. 2017) under the tenet that a large fraction of leaf nutrients,  
593 and nitrogen in particular, are partitioned toward building and maintaining en-  
594 zymes that support photosynthetic capacity, such as Rubisco (Brix 1971; Gulmon  
595 and Chu 1981; Evans 1989; Kattge et al. 2009; Walker et al. 2014). Terrestrial  
596 biosphere models predict leaf nutrient content from soil nutrient availability based  
597 on the assumption that increasing soil nutrients generally increases leaf nutrients  
598 (Firn et al. 2019; Li et al. 2020; Liang et al. 2020) which, in the case of nitrogen,  
599 generally corresponds with an increase in photosynthetic processes (Li et al. 2020;  
600 Liang et al. 2020).

601       Recent work calls the generality of relationships between soil nutrient avail-  
602 ability, leaf nutrient content, and photosynthetic capacity into question, suggest-  
603 ing instead that leaf nutrients and photosynthetic capacity are better predicted as  
604 an integrated product of aboveground climate, leaf traits, and soil nutrient avail-  
605 ability, rather than soil nutrient availability alone (Dong et al. 2017; Dong et al.  
606 2020; Dong et al. 2022; Firn et al. 2019; Smith et al. 2019; Peng et al. 2021).  
607 It has been reasoned that this result is because plants allocate added nutrients to  
608 growth and storage rather than alterations in leaf chemistry (Smith et al. 2019),  
609 perhaps as a result of nutrient limitation of primary productivity (LeBauer and  
610 Treseder 2008; Fay et al. 2015). Additionally, recent work suggests that relation-  
611 ships between leaf nutrient content and photosynthesis vary across environments,

612 and that the proportion of leaf nutrient content allocated to photosynthetic tis-  
613 sue varies over space and time with plant acclimation and adaptation responses  
614 to light availability, vapor pressure deficit, soil pH, soil nutrient availability, and  
615 environmental factors that influence leaf mass per area (Pons and Pearcy 1994;  
616 Niinemets and Tenhunen 1997; Evans and Poorter 2001; Hikosaka and Shigeno  
617 2009; Ghimire et al. 2017; Onoda et al. 2017; Luo et al. 2021). The use of linear  
618 relationships between leaf nutrient content and  $V_{cmax}$  to predict photosynthetic  
619 capacity, as commonly used in terrestrial biosphere models (Rogers 2014), is not  
620 capable of detecting such responses.

621 Photosynthetic least-cost theory provides an alternative framework for un-  
622 derstanding relationships between soil nutrient availability, leaf nutrient content,  
623 and photosynthetic capacity (Harrison et al. 2021). Leveraging a two-input mi-  
624 croeconomics approach (Wright et al. 2003), the theory posits that plants accli-  
625 mate to a given environment by optimizing leaf photosynthesis rates at the lowest  
626 summed cost of using nutrients and water (Prentice et al. 2014; Wang et al. 2017;  
627 Smith et al. 2019; Paillassa et al. 2020). Across resource availability gradients,  
628 the theory predicts that optimal photosynthetic rates can be achieved by trading  
629 less efficient use of a resource that is less costly to acquire (or more abundant)  
630 for more efficient use of a resource more costly to acquire (or less abundant). For  
631 example, an increase in soil nutrient availability should reduce the cost of acquir-  
632 ing and using nutrients (Bae et al. 2015; Eastman et al. 2021; Perkowski et al.  
633 2021), which could increase leaf nutrient investments in photosynthetic proteins to  
634 allow similar photosynthetic rates to be achieved with higher nutrient use (lower  
635 nutrient use efficiency) but lower water use (greater water use efficiency). The

636 theory suggests similar tradeoffs in response to increasing soil pH (Paillassa et al.  
637 2020), specifically, that increasing soil pH should reduce the cost of acquiring soil  
638 nutrients due to an increase in plant-available nutrient concentration (Paillassa  
639 et al. 2020; Dong et al. 2022). The theory is also capable of reconciling dynamic  
640 leaf nutrient-photosynthesis relationships at global scales (Luo et al. 2021).

641 Patterns expected from photosynthetic least-cost theory have recently re-  
642 ceived empirical support both in global environmental gradient (Smith et al.  
643 2019; Paillassa et al. 2020; Luo et al. 2021; Querejeta et al. 2022; Wester-  
644 band et al. 2023) and local manipulative invasion (Bialic-Murphy et al. 2021)  
645 studies. However, nutrient addition experiments that directly examine nutrient-  
646 water use tradeoffs expected from the theory are rare (but see Guerrieri et al.  
647 2011), and only global gradient studies testing the theory have considered soil pH  
648 in their analyses. As a result, there is a need to use nutrient addition and soil pH  
649 manipulation experiments to test mechanisms driving responses predicted by the  
650 theory.

651 In this study, I measured leaf responses to soil nitrogen availability in five  
652 deciduous tree species growing in the upper canopy of mature closed canopy tem-  
653 perate forests in the northeastern United States. Soil nitrogen availability and pH  
654 were manipulated through a nitrogen-by-pH field manipulation experiment with  
655 treatments applied since 2011, eight years prior to measurement. Two different soil  
656 nitrogen treatments were applied to increase nitrogen availability with opposing  
657 effects on soil pH. An additional nitrogen-free acidifying treatment was expected  
658 to decrease soil pH. I hypothesized that increased soil nitrogen availability would  
659 enable plants to increase nutrient uptake and create more photosynthetic enzymes

660 per leaf, allowing similar photosynthetic rates achieved with lower leaf C<sub>i</sub>:C<sub>a</sub> and  
661 increased leaf nitrogen content allocated to photosynthetic leaf tissue. I expected  
662 that this response would be driven by a reduction in the cost of acquiring nitrogen,  
663 which would cause trees to sacrifice efficient nitrogen use to enable more efficient  
664 use of other limiting resources (i.e., water). Finally, I hypothesized similar leaf  
665 responses to increasing soil pH.

666 3.2 Methods

667 3.2.1 *Study site description*

668 I conducted this study in summer 2019 at three stands located within a 20-km ra-  
669 dius of Ithaca, NY, USA (42.444 °N, 76.502 °W). All stands contain mature,  
670 closed-canopy forests dominated by deciduous tree species. Stands contained  
671 abundant sugar maple (*Acer saccharum* Marshall), American beech (*Fagus gran-*  
672 *difolia* Ehrh.), and white ash (*Fraxinus americana* L.), accounting for 43%, 15%,  
673 and 17% of the total aboveground biomass across the three stands, respectively,  
674 with less frequent red maple (*Acer rubrum* L.; 9% of total aboveground biomass)  
675 and red oak occurrences (*Quercus rubra* L.; 10% of total aboveground biomass).  
676 Soils at each site were broadly classified as a channery silt loam Inceptisols using  
677 the USDA NRCS Web Soil Survey data product (Soil Survey Staff 2022). Between  
678 2006 and 2020, study sites averaged 972 mm of precipitation per year and had an  
679 average temperature of 7.9 °C per a weather station located near the Cornell Uni-  
680 versity campus (42.449 °N, 76.449 °W) part of the NOAA NCEI Global Historical  
681 Climatology Network (Menne et al. 2012).

**682** 3.2.2 *Experimental design*

**683** Four 40 m x 40 m plots were set up at each site in 2009, each with an additional  
**684** 10 m buffer along plot perimeters (60 m x 60 m total). The plots were set up as a  
**685** nitrogen-by-pH field manipulation experiment, with one each of four treatments  
**686** at each site. Two nitrogen treatments were applied, both at  $50 \text{ kg N ha}^{-1} \text{ yr}^{-1}$ , as  
**687** either sodium nitrate ( $\text{NaNO}_3$ ) to raise soil pH, or ammonium sulfate ( $(\text{NH}_4)_2\text{SO}_4$ )  
**688** to acidify; an elemental sulfur treatment was selected to acidify without nitrogen,  
**689** applied at the same rate of S addition ( $57 \text{ kg S ha}^{-1} \text{ yr}^{-1}$ ); and control plots  
**690** received no additions. All amendments were added in pelletized form using hand-  
**691** held fertilizer spreaders to both the main plots and buffers. Amendments were  
**692** divided into three equal doses distributed across the growing season from 2011-  
**693** 2017 and added as a single dose from 2018 onward. During 2019, plots were  
**694** fertilized during the week of May 20.

**695** 3.2.3 *Leaf gas exchange and trait measurements*

**696** I sampled one leaf each from 6 to 10 individuals per plot between June 25 and July  
**697** 12, 2019 for gas exchange measurements (Table B1). Leaves were collected from  
**698** deciduous broadleaf trees represented across all sites and plots and were replicated  
**699** in efforts to mimic the species abundance of each plot at each site. I attempted  
**700** to collect leaves from the upper canopy to reduce differential shading effects on  
**701** leaf physiology. Leaves were accessed by pulling down small branches using an  
**702** arborist's slingshot and weighted beanbag attached to a throw line. Branches  
**703** were immediately recut under deionized water and remained submerged to reduce  
**704** stomatal closure and avoid xylem embolism, as done in Smith and Dukes (2018),

705 until gas exchange data were collected.

706 Randomly selected leaves with little to no visible external damage were  
707 attached to a Li-COR LI-6800 (Li-COR Bioscience, Lincoln, Nebraska, USA)  
708 portable photosynthesis machine to measure net photosynthesis ( $A_{\text{net}}$ ;  $\mu\text{mol m}^{-2}$   
709  $\text{s}^{-1}$ ), stomatal conductance ( $g_{\text{sw}}$ ;  $\text{mol m}^{-2} \text{s}^{-1}$ ), and intercellular  $\text{CO}_2$  concentra-  
710 tion ( $C_i$ ;  $\mu\text{mol mol}^{-1}$ ) at different reference  $\text{CO}_2$  concentrations ( $C_a$ ;  $\mu\text{mol mol}^{-1}$ )  
711 concentrations (i.e., an  $A_{\text{net}}/C_i$  curve) under saturating light conditions (2,000  
712  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ). Reference  $\text{CO}_2$  concentrations followed the sequence: 400, 300,  
713 200, 100, 50, 400, 400, 600, 800, 1000, 1200, 1500, and 2000  $\mu\text{mol mol}^{-1} \text{CO}_2$ . Leaf  
714 temperatures were not controlled in the cuvette and ranged from 21.8 °C to 31.7  
715 °C (mean±SD: 27.2±2.2 °C). A linear and second order log-polynomial nonlinear  
716 regression suggested no effect of temperature on stomatal conductance measured  
717 at 400  $\mu\text{mol mol}^{-1} \text{CO}_2$  or net photosynthesis measured at 400  $\mu\text{mol mol}^{-1} \text{CO}_2$   
718 (Table B2, B3; Fig. B1). All  $A_{\text{net}}/C_i$  curves were generated within one hour of  
719 branch severance.

720 Leaf morphological and chemical traits were collected on the same leaf used  
721 to generate each  $A_{\text{net}}/C_i$  curve. Images of each leaf were taken using a flat-bed  
722 scanner to determine fresh leaf area using the ‘LeafArea’ R package (Katabuchi  
723 2015), which automates leaf area calculations using ImageJ software (Schneider  
724 et al. 2012). Each leaf was dried at 65°C for at least 48 hours, weighed, and  
725 ground using a Retsch MM200 ball mill grinder (Verder Scientific, Inc., Newtown,  
726 PA, USA) until homogenized. Leaf mass per unit leaf area ( $M_{\text{area}}$ ,  $\text{g m}^{-2}$ ) was  
727 calculated as the ratio of dry leaf biomass to fresh leaf area. Using a subsample  
728 of ground and homogenized leaf biomass, leaf nitrogen content ( $N_{\text{mass}}$ ;  $\text{gN g}^{-1}$ )

**729** and leaf  $\delta^{13}\text{C}$  (‰, relative to Vienna Pee Dee Belemnite international reference  
**730** standard) were measured at the Cornell Stable Isotope Lab with an elemental  
**731** analyzer (NC 2500, CE Instruments, Wigan, UK) interfaced to an isotope ratio  
**732** mass spectrometer (Delta V Isotope Ratio Mass Spectrometer, ThermoFisher Sci-  
**733** entific, Waltham, MA, USA). Leaf nitrogen content per unit leaf area ( $N_{\text{area}}$ ; g N  
**734**  $\text{m}^{-2}$ ) was calculated by multiplying  $N_{\text{mass}}$  by  $M_{\text{area}}$ .

**735** I used leaf  $\delta^{13}\text{C}$  values to estimate  $\chi$  (unitless), which is an isotope-derived  
**736** estimate of the leaf  $C_i:C_a$  ratio. While intercellular and atmospheric  $\text{CO}_2$  concen-  
**737** trations were directly measured during each  $A_{\text{net}}/C_i$  curve, deriving  $\chi$  from  $\delta^{13}\text{C}$   
**738** provides a more integrative estimate of the leaf  $C_i:C_a$  over an individual leaf's  
**739** lifespan. I derived  $\chi$  following the approach of Farquhar et al. (1989) described  
**740** in Cernusak et al. (2013):

$$\chi = \frac{\Delta^{13}\text{C} - a}{b - a} \quad (3.1)$$

**741** where  $\Delta^{13}\text{C}$  represents the relative difference between leaf  $\delta^{13}\text{C}$  (‰) and air  $\delta^{13}\text{C}$   
**742** (‰), and is calculated from the following equation:

$$\Delta^{13}\text{C} = \frac{\delta^{13}\text{C}_{\text{air}} - \delta^{13}\text{C}_{\text{leaf}}}{1 + \delta^{13}\text{C}_{\text{leaf}}} \quad (3.2)$$

**743** where  $\delta^{13}\text{C}_{\text{air}}$  is assumed to be -8‰ (Keeling et al. 1979; Farquhar et al. 1989),  $a$   
**744** represents the fractionation between  $^{12}\text{C}$  and  $^{13}\text{C}$  due to diffusion in air, assumed  
**745** to be 4.4‰, and  $b$  represents the fractionation caused by Rubisco carboxylation,  
**746** assumed to be 27‰ (Farquhar et al. 1989).

**747** 3.2.4  $A_{net}/C_i$  curve-fitting and parameter estimation

**748** I fit  $A_{net}/C_i$  curves of each individual using the ‘fitaci’ function in the ‘plante-  
**749** cophys’ R package (Duursma 2015). This function estimates the maximum rate  
**750** of Rubisco carboxylation ( $V_{cmax}$ ;  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ) and maximum rate of electron  
**751** transport for RuBP regeneration ( $J_{max}$ ;  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ) based on the Farquhar,  
**752** von Caemmerer, and Berry biochemical model of C<sub>3</sub> photosynthesis (Farquhar  
**753** et al. 1980). For each curve fit, I included triose phosphate utilization (TPU)  
**754** limitation to avoid underestimating  $J_{max}$  (Gregory et al. 2021). Curves were  
**755** visually examined to confirm the likely presence of TPU limitation.

**756** I determined Michaelis-Menten coefficients for Rubisco affinity to CO<sub>2</sub> ( $K_c$ ;  
**757**  $\mu\text{mol mol}^{-1}$ ) and O<sub>2</sub> ( $K_o$ ;  $\mu\text{mol mol}^{-1}$ ), and the CO<sub>2</sub> compensation point ( $\Gamma^*$ ;  
**758**  $\mu\text{mol mol}^{-1}$ ) using leaf temperature and equations described in Medlyn et al.  
**759** (2002) and derived in Bernacchi et al. (2001). Specifically,  $K_c$  and  $K_o$  were  
**760** calculated as:

$$K_c = 404.9 * \exp^{\frac{79430(T_k - 298)}{298RT_k}} \quad (3.3)$$

**761** and

$$K_o = 278.4 * \exp^{\frac{36380(T_k - 298)}{298RT_k}} \quad (3.4)$$

**762** while  $\Gamma^*$  was calculated as:

$$\Gamma^* = 42.75 * \exp^{\frac{37830(T_k - 298)}{298RT_k}} \quad (3.5)$$

**763** In all three equations,  $T_k$  is the leaf temperature (in Kelvin) during each  $A_{\text{net}}/C_i$

**764** curve and R is the universal gas constant ( $8.314 \text{ J mol}^{-1} \text{ K}^{-1}$ ).

**765** I standardized  $V_{\text{cmax}}$  and  $J_{\text{max}}$  estimates to  $25^\circ\text{C}$  using a modified Arrhe-

**766** nius equation (Kattge and Knorr 2007):

$$k_{25} = \frac{k_{\text{obs}}}{e^{\frac{H_a(T_{\text{obs}} - T_{\text{ref}})}{T_{\text{ref}}RT_{\text{obs}}}} * \frac{1+e^{\frac{T_{\text{ref}}\Delta S - H_d}{T_{\text{obs}}\Delta S - H_d}}}{1+e^{\frac{T_{\text{obs}}\Delta S - H_d}{T_{\text{obs}}\Delta S - H_d}}}} \quad (3.6)$$

**767**  $k_{25}$  represents the standardized  $V_{\text{cmax}}$  or  $J_{\text{max}}$  rate at  $25^\circ\text{C}$ ,  $k_{\text{obs}}$  represents the

**768**  $V_{\text{cmax}}$  or  $J_{\text{max}}$  estimate at the average leaf temperature measured inside the cuvette

**769** during the  $A_{\text{net}}/C_i$  curve.  $H_a$  is the activation energy of  $V_{\text{cmax}}$  ( $71,513 \text{ J mol}^{-1}$ )

**770** Kattge and Knorr (2007) or  $J_{\text{max}}$  ( $49,884 \text{ J mol}^{-1}$ ) (Kattge and Knorr 2007).

**771**  $H_d$  represents the deactivation energy of both  $V_{\text{cmax}}$  and  $J_{\text{max}}$  ( $200,000 \text{ J mol}^{-1}$ )

**772** (Medlyn et al. 2002), and R represents the universal gas constant ( $8.314 \text{ J mol}^{-1}$

**773**  $\text{K}^{-1}$ ).  $T_{\text{ref}}$  represents the standardized temperature of  $298.15 \text{ K}$  ( $25^\circ\text{C}$ ) and  $T_{\text{obs}}$

**774** represents the mean leaf temperature (in K) during each  $A_{\text{net}}/C_i$  curve.  $\Delta S$  is an

**775** entropy term that (Kattge and Knorr 2007) derived as a linear relationship with

**776** average growing season temperature ( $T_g$ ;  $^\circ\text{C}$ ), where:

$$\Delta S_{v_{\text{cmax}}} = -1.07 T_g + 668.39 \quad (3.7)$$

**777** and

$$\Delta S_{j_{\text{max}}} = -0.75 T_g + 659.70 \quad (3.8)$$

**778** I estimated  $T_g$  in Equations 3.7 and 3.8 based on mean daily (24-hour) air tem-  
**779** perature of the 30 days leading up to the day of each sample collection using the  
**780** same weather station reported in the site description. I used  $V_{cmax25}$  and  $J_{max25}$   
**781** estimates to calculate the ratio of  $J_{max25}$  to  $V_{cmax25}$  ( $J_{max25}:V_{cmax25}$ ; unitless).

**782** 3.2.5 *Proportion of leaf nitrogen allocated to photosynthesis and structure*

**783** I used equations from Niinemets and Tenhunen (1997) to estimate the proportion  
**784** of leaf nitrogen content allocated to Rubisco and bioenergetics. The proportion of  
**785** leaf nitrogen allocated to Rubisco ( $\rho_{rubisco}$ ; gN gN $^{-1}$ ) was calculated as a function  
**786** of  $V_{cmax25}$  and  $N_{area}$ :

$$\rho_{rubisco} = \frac{V_{cmax25} N_r}{V_{cr} N_{area}} \quad (3.9)$$

**787** where  $N_r$  is the amount of nitrogen in Rubisco, set to 0.16 gN (gN in Rubisco) $^{-1}$   
**788** and  $V_{cr}$  is the maximum rate of RuBP carboxylation per unit Rubisco protein,  
**789** set to 20.5  $\mu$ mol CO<sub>2</sub> (g Rubisco) $^{-1}$ . The proportion of leaf nitrogen allocated to  
**790** bioenergetics ( $\rho_{bioe}$ ; gN gN $^{-1}$ ) was similarly calculated as a function of  $J_{max25}$  and  
**791**  $N_{area}$ :

$$\rho_{bioe} = \frac{J_{max25} N_b}{J_{mc} N_{area}} \quad (3.10)$$

**792** where  $N_b$  is the amount of nitrogen in cytochrome f, set to 0.12407 gN ( $\mu$ mol  
**793** cytochrome f) $^{-1}$  assuming a constant 1: 1: 1.2 cytochrome f: ferredoxin NADP  
**794** reductase: coupling factor molar ratio (Evans and Seemann 1989; Niinemets and  
**795** Tenhunen 1997), and  $J_{mc}$  is the capacity of electron transport per cytochrome f,

**796** set to 156  $\mu\text{mol}$  electron ( $\mu\text{mol}$  cytochrome f) $^{-1}\text{s}^{-1}$ .

**797** I estimated the proportion of leaf nitrogen content allocated to photosynthetic tissue ( $\rho_{\text{photo}}$ ;  $\text{gN gN}^{-1}$ ) as the sum of  $\rho_{\text{rubisco}}$  and  $\rho_{\text{bioe}}$ . This calculation  
**798** is an underestimate of the proportion of leaf nitrogen allocated to photosynthetic  
**799** tissue because it does not include nitrogen allocated to light harvesting proteins.  
**800** This leaf nitrogen pool was not included because I did not perform chlorophyll  
**801** extractions on focal leaves. However, the proportion of leaf nitrogen content al-  
**802** located to light harvesting proteins tends to be small relative to  $\rho_{\text{rubisco}}$  and  $\rho_{\text{bioe}}$ ,  
**803** and may scale with changes in  $\rho_{\text{rubisco}}$  and  $\rho_{\text{bioe}}$  (Niinemets and Tenhunen 1997).

**805** Finally, the proportion of leaf nitrogen content allocated to structural tissue  
**806** ( $\rho_{\text{structure}}$ ;  $\text{gN gN}^{-1}$ ) was estimated as:

$$\rho_{\text{structure}} = \frac{N_{\text{cw}}}{N_{\text{area}}} \quad (3.11)$$

**807** where  $N_{\text{cw}}$  is the leaf nitrogen content allocated to cell walls ( $\text{gN m}^{-2}$ ), calculated  
**808** as a function of  $M_{\text{area}}$  using an empirical equation from Onoda et al. (2017):

$$N_{\text{cw}} = 0.000355 * M_{\text{area}}^{1.39} \quad (3.12)$$

### **809** 3.2.6 *Tradeoffs between nitrogen and water use*

**810** Photosynthetic nitrogen use efficiency (PNUE;  $\mu\text{mol CO}_2 \text{ mol}^{-1} \text{ N s}^{-1}$ ) was cal-  
**811** culated by dividing  $A_{\text{net}}$  by  $N_{\text{area}}$ , first converting  $N_{\text{area}}$  to  $\text{mol N m}^{-2}$  using the  
**812** molar mass of nitrogen ( $14 \text{ g mol}^{-1}$ ). I used  $\chi$  as an indicator of water use effi-  
**813** ciency, which exploratory analyses suggest had similar responses to soil nitrogen

814 availability and pH as intrinsic water use efficiency measured from gas exchange  
815 ( $A_{\text{net}}/g_{\text{sw}}$ ). Tradeoffs between nitrogen and water use were determined by cal-  
816 culating the ratio of  $N_{\text{area}}$  to  $\chi$  ( $N_{\text{area}}:\chi$ ; gN m<sup>-2</sup>) and  $V_{\text{cmax25}}$  to  $\chi$  ( $V_{\text{cmax25}}:\chi$ ;  
817  $\mu\text{mol m}^{-2} \text{ s}^{-1}$ ). This approach is similar to tradeoff calculations in which nitrogen-  
818 water use tradeoffs are measured as the ratio of  $N_{\text{area}}$  or  $V_{\text{cmax25}}$  to  $g_{\text{sw}}$  (Paillassa  
819 et al. 2020; Bialic-Murphy et al. 2021). In this chapter, I quantify these rela-  
820 tionships using  $\chi$  in lieu of  $g_{\text{sw}}$  because  $g_{\text{sw}}$  rapidly changes with environmental  
821 conditions and therefore may have been altered by recent tree branch severance  
822 and/or placement in the cuvette.

### 823 3.2.7 *Soil nitrogen availability and pH*

824 To characterize soil nitrogen availability at the time of our leaf gas exchange  
825 measurements, I used mixed bed resin bags to quantify mobile ammonium-N and  
826 nitrate-N concentrations in each plot. Lycra mesh bags were filled with 5 g of  
827 Dowex® Marathon MR-3 hydrogen and hydroxide form resin (MilliporeSigma,  
828 Burlington, MA USA) and sealed with a zip tie. Each bag was activated by  
829 soaking in 0.5 M HCl for 20 minutes, then in 2 M NaCl until pH of the saline  
830 solution stabilized, as described in Allison et al. (2008). Five resin bags were  
831 inserted about 10 cm below the soil surface at each plot on June 25, 2019: one  
832 near each of the four plot corners and one near the plot center. All resin bags  
833 were collected 24 days later on July 19, 2019 and were frozen until extracted.

834 Prior to anion and cation extraction, each resin bag was rinsed with ul-  
835 trapure water (MilliQ IQ 7000; Millipore Sigma, Burlington, MA) to remove any  
836 surface soil residues. Anions and cations were extracted from surface-cleaned

837 resin bags by individually soaking and shaking each bag in 100 mL of a 0.1 M  
838 HCl/2.0 M NaCl matrix for one hour. Using a microplate reader (Biotek Synergy  
839 H1; Biotek Instruments, Winooski, VT USA), I quantified nitrate-N concentra-  
840 tions spectrophotometrically at 540 nm with the end product of a single reagent  
841 vanadium (III) chloride reaction (Doane and Horwáth 2003), and ammonium-N  
842 concentrations quantified at 650 nm with the end product of a modified phenol-  
843 hypochlorite reaction (Weatherburn 1967; Rhine et al. 1998). Both the single  
844 reagent vanadium (III) chloride and modified phenol-hypochlorite methodologies  
845 are well established for determining nitrate-N and ammonium-N concentrations  
846 in resin bag extracts (Arnone 1997; Allison et al. 2008). I used a series of nega-  
847 tive and positive controls throughout each well plate to verify the accuracy and  
848 precision of our measurements, assaying each resin bag extract and control in  
849 triplicate. Soil nitrogen availability was estimated as the sum of the nitrate-N  
850 and ammonium-N concentration in each resin bag, normalized per g of resin and  
851 duration in the field ( $\mu\text{g N g}^{-1}$  resin  $\text{d}^{-1}$ ), then subsequently averaged across all  
852 resin bags in a plot for a plot-level mean.

853 Soil pH was measured on 0-10 cm mineral soil samples collected prior to  
854 fertilization in 2019. Near each of the four plot corners, three 5.5 cm diameter soil  
855 cores were collected after first removing the forest floor where present. Each set  
856 of three cores was placed in a plastic bag, and later composited by hand mixing  
857 and sieved to 4 mm. Soil pH was determined for a 1:2 soil:water slurry (10 g  
858 field-moist soil to 20 mL DI water) of each sample using an Accumet AB15 pH  
859 meter with flushable junction probe (Fisher Scientific; Hampton, NH, USA), and  
860 was estimated at the plot level as the mean soil pH within each plot.

**861** 3.2.8 *Statistical analyses*

**862** I built two separate series of linear mixed-effects models to explore effects of soil  
**863** nitrogen availability, soil pH, species, and leaf nitrogen content on leaf physiolog-  
**864** ical traits. In the first series of linear mixed-effects models, I explored the effect  
**865** of soil nitrogen availability, soil pH, and species on leaf nitrogen content, leaf  
**866** photosynthesis, stomatal conductance, and nitrogen-water use tradeoffs. Models  
**867** included plot-level soil nitrogen availability and plot-level soil pH as continuous  
**868** fixed effects, species as a categorical fixed effect, and site as a categorical ran-  
**869** dom intercept term. Interaction terms between fixed effects were not included  
**870** due to the small number of experimental plots. I built a series of separate mod-  
**871** els with this independent variable structure to quantify individual effects of soil  
**872** nitrogen availability, soil pH, and species on  $N_{\text{area}}$ ,  $M_{\text{area}}$ ,  $N_{\text{mass}}$ ,  $A_{\text{net}}$ ,  $V_{\text{cmax25}}$ ,  
**873**  $J_{\text{max25}}$ ,  $J_{\text{max25}}:V_{\text{cmax25}}$ ,  $\rho_{\text{rubisco}}$ ,  $\rho_{\text{bioenergetics}}$ ,  $\rho_{\text{photo}}$ ,  $\rho_{\text{structure}}$ ,  $\chi$ , PNUE,  $N_{\text{area}}:\chi$ , and  
**874**  $V_{\text{cmax25}}:\chi$ .

**875** A second series of linear mixed-effects models were built to investigate  
**876** relationships between leaf nitrogen content and photosynthetic parameters. Sta-  
**877** tistical models included  $N_{\text{area}}$  as a single continuous fixed effect with species and  
**878** site designated as individual random intercept terms. I used this independent  
**879** variable structure to quantify individual effects of leaf nitrogen content on  $A_{\text{net}}$ ,  
**880**  $V_{\text{cmax25}}$ ,  $J_{\text{max25}}$ ,  $J_{\text{max25}}:V_{\text{cmax25}}$ , and  $\chi$ .

**881** For all linear mixed-effects models, I used Shapiro-Wilk tests of normality  
**882** to determine whether linear mixed-effects models satisfied residual normality as-  
**883** sumptions. If residual normality assumptions were not met, then models were fit  
**884** using dependent variables that were natural log transformed. If residual normal-

885 ity assumptions were still not met (Shapiro-Wilk:  $p<0.05$ ), then models were fit  
886 using dependent variables that were square root transformed. All residual nor-  
887 mality assumptions for both sets of models that did not originally satisfy residual  
888 normality assumptions were met with either a natural log or square root data  
889 transformation (Shapiro-Wilk:  $p>0.05$  in all cases).

890 In the first series of models, models for  $N_{\text{area}}$ ,  $M_{\text{area}}$ ,  $N_{\text{mass}}$ ,  $V_{\text{cmax25}}$ ,  $J_{\text{max25}}$ ,  
891  $\chi$ ,  $N_{\text{area}}:\chi$ , and  $V_{\text{cmax25}}:\chi$ ,  $\rho_{\text{rubisco}}$ ,  $\rho_{\text{bioenergetics}}$ ,  $\rho_{\text{photo}}$ ,  $\rho_{\text{structure}}$  satisfied residual  
892 normality assumptions without data transformations (Shapiro-Wilk:  $p>0.05$  in  
893 all cases). The model for  $J_{\text{max25}}:V_{\text{cmax25}}$  satisfied residual normality assumptions  
894 with a natural log data transformation, while models for  $A_{\text{net}}$  and PNUE each  
895 satisfied residual normality assumptions with square root data transformations.  
896 In the second series of models, models for  $V_{\text{cmax25}}$ ,  $J_{\text{max25}}$ ,  $\chi$ , and  $V_{\text{cmax25}}:\chi$  satis-  
897 fied residual normality assumptions without data transformations (Shapiro-Wilk:  
898  $p>0.05$  in all cases). The model for  $J_{\text{max25}}:V_{\text{cmax25}}$  required a natural log data  
899 transformation and the model for  $A_{\text{net}}$  required a square root data transformation  
900 (Shapiro-Wilk:  $p>0.05$  in both cases).

901 In all models, I used the ‘lmer’ function in the ‘lme4’ R package (Bates  
902 et al. 2015) to fit each model and the ‘Anova’ function in the ‘car’ R package  
903 (Fox and Weisberg 2019) to calculate Type II Wald’s  $\chi^2$  and determine the signif-  
904 icance level ( $\alpha=0.05$ ) of each fixed effect coefficient. Finally, I used the ‘emmeans’  
905 R package (Lenth 2019) to conduct post-hoc comparisons using Tukey’s tests,  
906 where degrees of freedom were approximated using the Kenward-Roger approach  
907 (Kenward and Roger 1997). All analyses and plots were conducted in R version  
908 4.1.1 (R Core Team 2021). All figure regression lines and associated 95% confi-

**909** dence interval error bars were plotted using predictions generated across the soil  
**910** nitrogen availability gradient using the ‘emmeans’ R package (Lenth 2019).

**911** 3.3 Results

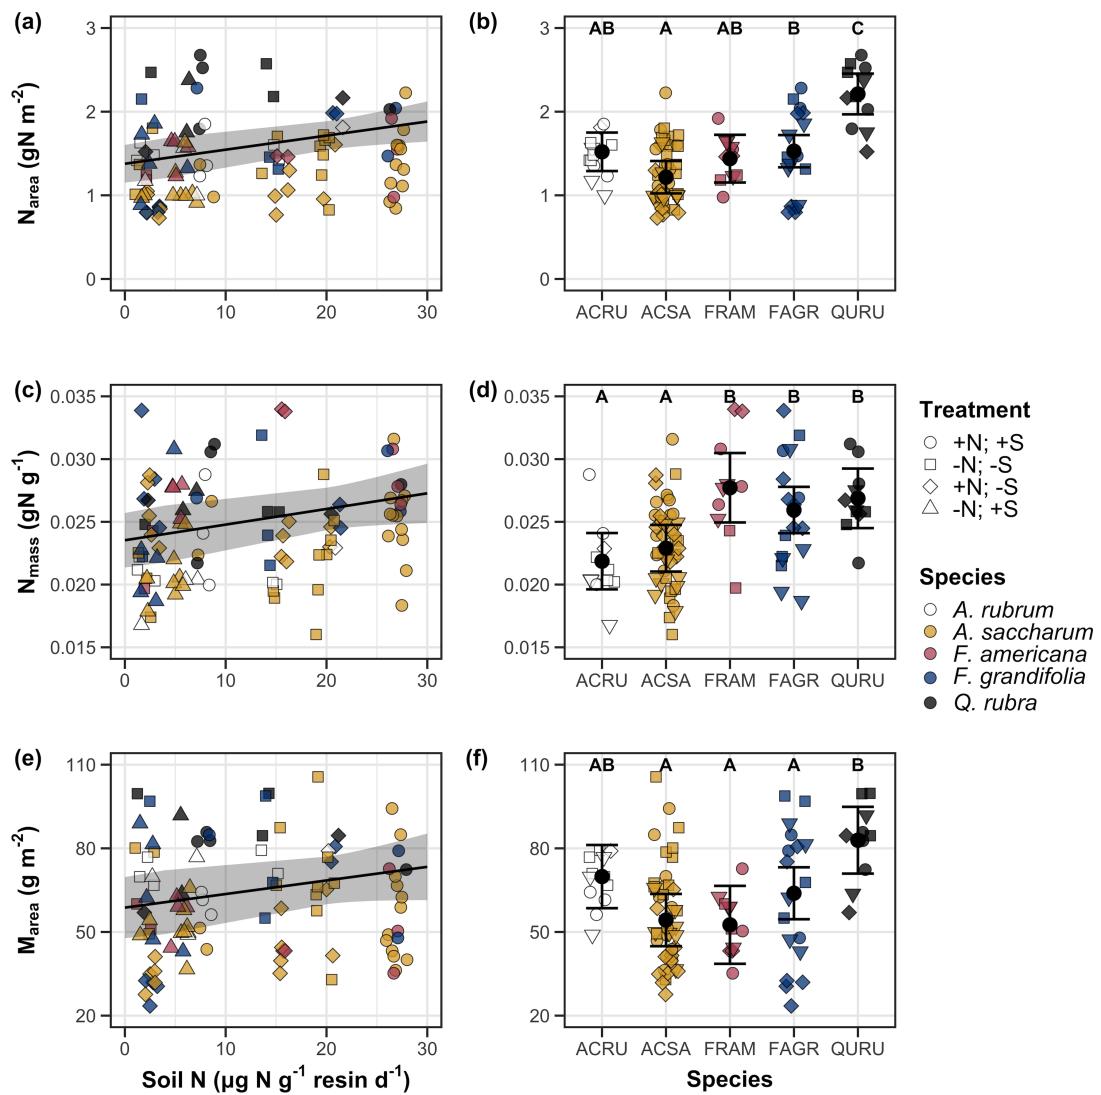

**912** 3.3.1 *Leaf nitrogen content*

**913** Increasing soil nitrogen availability generally increased  $N_{\text{area}}$  (Table 3.1; Fig. 3.1a).  
**914** This pattern was driven by an increase in  $N_{\text{mass}}$  (Table 3.1; Fig. 3.1c) and a  
**915** marginal increase in  $M_{\text{area}}$  (Table 3.1; Fig. 3.1e) with increasing soil nitrogen  
**916** availability. There was no effect of soil pH on  $N_{\text{area}}$ ,  $N_{\text{mass}}$ , or  $M_{\text{area}}$  (Table 3.1);  
**917** however, I also observed strong differences in  $N_{\text{area}}$  (Fig. 3.1b),  $N_{\text{mass}}$  (Fig. 3.1d),  
**918** and  $M_{\text{area}}$  (Fig. 3.1e) between species (Table 3.1).

**Table 3.1.** Effects of soil nitrogen availability, soil pH, and species on leaf nitrogen content per unit leaf area ( $N_{\text{area}}$ ; gN m<sup>-2</sup>), leaf nitrogen content per unit leaf mass ( $N_{\text{mass}}$ ; gN g<sup>-1</sup>), and leaf mass per unit leaf area ( $M_{\text{area}}$ ; g m<sup>-2</sup>)\*

**Figure 3.1.** Effects of soil N availability and species on leaf nitrogen content per unit leaf area (a-b), leaf nitrogen content per unit leaf biomass (c-d), and leaf mass per unit leaf area (e-f). Soil nitrogen availability is represented on the x-axis in the left column of panels, while species is represented on the x-axis in the right column of panels. Tree species are represented as colored points and treatment plots are represented as shaped points, jittered for visibility. Species are abbreviated in the right column of panels through their assigned NRCS PLANTS Database symbol (USDA NRCS 2022), grouped along the x-axis per common mycorrhizal association, where the first three species commonly associate with arbuscular mycorrhizae (ACRU, ACSA, FAGR) and the second two species with ectomycorrhizae (FAGR, QURU). Trendlines are only included when the regression slope is statistically different from zero ( $p < 0.05$ ).

**920** 3.3.2 *Net photosynthesis and leaf biochemistry*

**921** Increasing soil nitrogen availability generally had no effect on  $A_{\text{net}}$ ,  $V_{\text{cmax25}}$ ,  $J_{\text{max25}}$ ,  
**922** or  $J_{\text{max25}}:V_{\text{cmax25}}$  (Table 3.2, Figs. 3.2a, 3.2d, 3.2g). I also observed strong species  
**923** effects on all measured leaf photosynthetic traits (Table 3.2; Figs. 3.2b, 3.2e, 3.2h).  
**924** Increasing soil pH had a marginal negative effect on  $A_{\text{net}}$ , but had no effect on  
**925**  $V_{\text{cmax25}}$ ,  $J_{\text{max25}}$ , or  $J_{\text{max25}}:V_{\text{cmax25}}$  (Table 3.2). There was a weak positive effect of  
**926** increasing  $N_{\text{area}}$  on  $A_{\text{net}}$  (Fig. 3.2c), but quite strong positive effects of increasing  
**927**  $N_{\text{area}}$  on  $V_{\text{cmax25}}$  and  $J_{\text{max25}}$  (Table 3.2; Fig. 3.2f and 3.2i).

**Table 3.2.** Effects of soil nitrogen availability, soil pH, species, and  $N_{\text{area}}$  on net photosynthesis ( $A_{\text{net}}$ ;  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ), the maximum rate of Rubisco carboxylation ( $V_{\text{cmax25}}$ ;  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ), the maximum rate of RuBP regeneration ( $J_{\text{max25}}$ ;  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ), and the ratio of the maximum rate of RuBP regeneration to the maximum rate of Rubisco carboxylation ( $J_{\text{max25}}:V_{\text{cmax25}}$ ; unitless)\*

928 \*Significance determined using Type II Wald  $\chi^2$  tests ( $\alpha=0.05$ ). P-values less than 0.05 are in bold, while p-values  
 929 between 0.05 and 0.1 are italicized. Superscript letters indicate model coefficients fit to natural-log (<sup>a</sup>) or square-root  
 930 (<sup>b</sup>) transformed data. Relationships between  $N_{\text{area}}$  and each response variable were fit using the second series of  
 931 bivariate mixed-effects models, so model coefficients and results are independent of model coefficients and results  
 932 reported for relationships between soil nitrogen, soil pH, and species for each response variable.

**Figure 3.2.** Effects of soil nitrogen availability (left column of panels), species (middle column of panels), and leaf nitrogen content per unit leaf area (right column of panels) on net photosynthesis (a-c), maximum Rubisco carboxylation rate (d-f), and maximum RuBP regeneration rate (g-i). Soil nitrogen availability is represented on the x-axis in the left column of panels, species is represented on the x-axis in the middle column of panels, and leaf nitrogen content per unit leaf area is represented continuously on the x-axis in the right column of panels. Species abbreviations and position along the x-axis in the middle column of panels, colored points, shapes, and trendlines are as explained in Figure 3.1.

**933** 3.3.3 *Leaf nitrogen allocation*

**934** Neither soil nitrogen availability nor soil pH affected the proportion of leaf nitrogen  
**935** allocated to Rubisco or bioenergetics (Table 3.3; Fig. 3.3a, Fig. 3.3c). There was  
**936** also no effect of soil nitrogen availability or soil pH on the proportion of leaf  
**937** nitrogen allocated to photosynthesis (Table 3.3; Fig. 3.3f). I found no effect of  
**938** soil nitrogen availability or soil pH on the proportion of leaf nitrogen allocated to  
**939** structure (Table 3.3; Fig 3.3g). Species varied in the proportion of leaf nitrogen  
**940** allocated to Rubisco, photosynthesis, and structure (Fig 3.3b, Fig. 3.3f, Fig 3.3h),  
**941** with no detectable species effect on the proportion of leaf nitrogen allocated to  
**942** bioenergetics (Table 3.3, Fig. 3.3d).

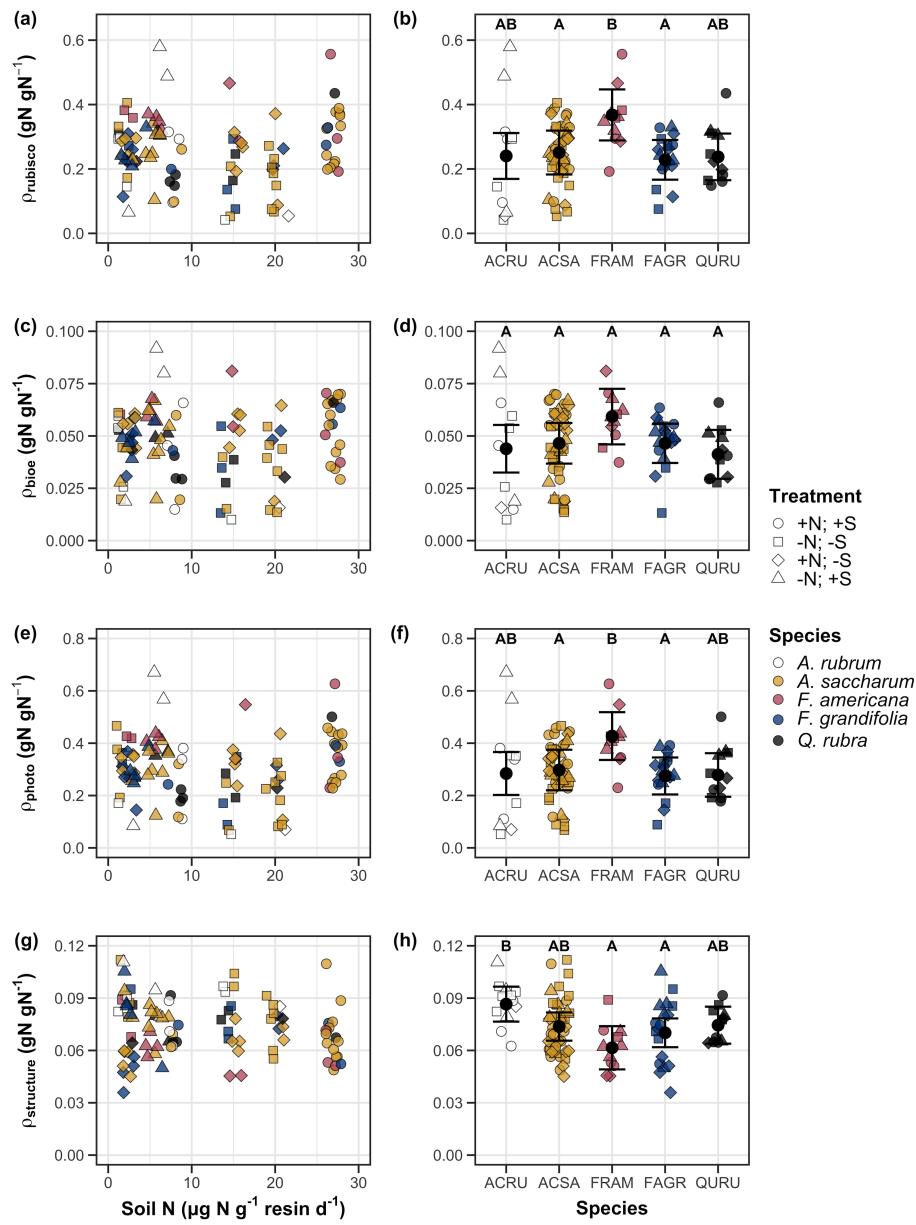

**Table 3.3.** Effects of soil nitrogen availability, soil pH, and species on the proportion of leaf nitrogen content allocated to photosynthesis ( $\rho_{\text{photo}}$ ; gN gN<sup>-1</sup>), Rubisco ( $\rho_{\text{rubisco}}$ ; gN gN<sup>-1</sup>), bioenergetics ( $\rho_{\text{bioe}}$ ; gN gN<sup>-1</sup>), and structure ( $\rho_{\text{structure}}$ ; gN gN<sup>-1</sup>)\*

**Figure 3.3.** Effects of soil nitrogen availability and species on the proportion of leaf nitrogen content allocated to Rubisco (a-b), bioenergetics (c-d), photosynthesis (e-f), and structure (g-h). Soil nitrogen availability is represented on the x-axis in the left column of panels and species are represented on the x-axis in the right column of panels. Species abbreviations and position along the x-axis in the middle column of panels, colored points, shapes, trendlines, error bars, and compact lettering are as explained in Figure 3.1.

**944** 3.3.4 *Tradeoffs between nitrogen and water use*

**945** Although soil nitrogen availability did not affect  $\chi$  (Table 3.4; Fig. 3.4a), increasing  
**946** soil nitrogen availability decreased PNUE (Table 3.4; Fig. 3.4d) and increased  
**947** the ratio of  $N_{\text{area}}:\chi$  (Table 3.4; Fig. 3.4f). Specifically, this response yielded a  
**948** 26% reduction in PNUE and 37% stimulation in  $N_{\text{area}}:\chi$  across the soil nitrogen  
**949** availability gradient. There was no apparent effect of soil nitrogen availability on  
**950**  $V_{\text{cmax25}}:\chi$  (Table 3.4; Fig. 3.4h). Increasing soil pH had a weak marginal nega-  
**951** tive effect on PNUE, but did not influence  $\chi$ ,  $N_{\text{area}}:\chi$ , or  $V_{\text{cmax25}}:\chi$  (Table 3.4). I  
**952** observed differences in  $\chi$  (Fig. 3.4b), PNUE (Fig. 3.4e),  $N_{\text{area}}:\chi$  (Fig. 3.4g), and  
**953**  $V_{\text{cmax25}}:\chi$  (Fig. 3.4i) between species (Table 3.4). Finally, increasing  $N_{\text{area}}$  had a  
**954** strong negative effect on  $\chi$  (Table 3.4; Fig. 3.4c) and a strong positive effect on  
**955**  $V_{\text{cmax25}}:\chi$  (Table 3.4; Fig. 3.4j).

**Table 3.4.** Effects of soil nitrogen availability, soil pH, species, and  $N_{\text{area}}$  on  $\chi$  (unitless), photosynthetic nitrogen use efficiency (PNUE;  $\mu\text{mol CO}_2 \text{ mol}^{-1} \text{ N s}^{-1}$ ), leaf nitrogen content per unit  $\chi$  ( $N_{\text{area}}:\chi$ ;  $\text{gN m}^{-2}$ ), and maximum Rubisco carboxylation rate per unit  $\chi$  ( $V_{\text{cmax25}}:\chi$ ;  $\mu\text{mol m}^{-2} \text{ s}^{-1}$ )<sup>\*</sup>

956 \*Significance determined using Type II Wald  $\chi^2$  tests ( $\alpha = 0.05$ ).  $P$ -values less than 0.05 are in bold, while  $p$ -values  
 957 between 0.05 and 0.1 are italicized. Superscript letters indicate model coefficients fit to natural-log<sup>(a)</sup> or square-root  
 958<sup>(b)</sup> transformed data. Relationships between  $N_{\text{area}}$  and each response variable were fit using the second series of  
 959 bivariate mixed-effects models, so model coefficients and results are independent of model coefficients and results  
 960 reported for relationships between soil nitrogen, soil pH, and species for each response variable.

**Figure 3.4.** Effects of soil nitrogen availability and species on the proportion of leaf nitrogen content allocated to Rubisco (a-b), bioenergetics (c-d), photosynthesis (Rubisco + bioenergetics; e-f), and structure (g-h). Soil nitrogen availability is represented on the x-axis in the left column of panels and species are represented on the x-axis in the right column of panels. Species abbreviations and position along the x-axis in the middle column of panels, colored points, shapes, trendlines, error bars, and compact lettering are as explained in Figure 3.1.

**961** 3.4 Discussion

**962** Photosynthetic least-cost theory provides an explanation for understanding rela-  
**963** tionships between soil nutrient availability, leaf nutrient allocation, and photosyn-  
**964** thetic capacity. The theory suggests that plants acclimate to a given environment  
**965** by optimizing leaf photosynthesis rates at the lowest summed cost of using nu-  
**966** trients and water (Prentice et al. 2014; Wang et al. 2017; Smith et al. 2019;  
**967** Paillassa et al. 2020). The theory predicts that an increase in soil nutrient avail-  
**968** ability should allow similar photosynthesis rates to be achieved with increased leaf  
**969** nutrient content and photosynthetic capacity (i.e.,  $V_{cmax25}$  and  $J_{max25}$ ) at lower  
**970** leaf  $C_i:C_a$  ( $\chi$ ), resulting in an increase in water use efficiency, decrease in nutri-  
**971** ent use efficiency, and increase in both leaf nutrient content and photosynthetic  
**972** capacity per unit  $\chi$ . The theory predicts similar leaf responses to increasing soil  
**973** pH under acidic conditions, presumably due to generally faster nutrient cycle dy-  
**974** namics and consequent reductions in the cost of acquiring nutrients relative to  
**975** water with increasing soil pH (Wang et al. 2017; Paillassa et al. 2020; Dong et al.  
**976** 2020).

**977** Supporting the theory, increasing soil nitrogen availability was associated  
**978** with increased leaf nitrogen content, a pattern that reduced photosynthetic nitro-  
**979** gen use efficiency and increased leaf nitrogen content per unit  $\chi$ . Increasing soil  
**980** nitrogen coincided with slight, but non-significant decreases in  $\chi$  and increases  
**981** in  $V_{cmax25}$  and  $J_{max25}$  ( $p<0.2$ , Table 3.2). The positive trend between soil ni-  
**982** trogen availability and photosynthetic capacity was supported by the concurrent  
**983** strong increase in leaf nitrogen content with increasing soil nitrogen availability,  
**984** which resulted in no change in the proportion of leaf nitrogen content allocated to

985 photosynthesis across the soil nitrogen availability gradient. Additionally, leaf ni-  
986 trogen content exhibited a strong negative correlation with  $\chi$ , indicative of strong  
987 nitrogen-water use tradeoffs at the leaf level. Responses tended to vary more due  
988 to soil nitrogen availability than soil pH. Overall, these findings are consistent  
989 with the nutrient-water use tradeoffs predicted from theory.

990 3.4.1 *Soil nitrogen availability modifies tradeoffs between nitrogen and water use*  
991 In support of expected least-cost outcomes and past environmental gradient stud-  
992 ies (Dong et al. 2017; Paillassa et al. 2020), increasing soil nitrogen availability  
993 was associated with increased leaf nitrogen content. Soil nitrogen availability had  
994 smaller impacts on measures of net photosynthesis and  $\chi$ , which led to reductions  
995 in PNUE and increases in leaf nitrogen content per unit  $\chi$ , as expected from the-  
996 ory. Photosynthetic least-cost theory suggests that reductions in PNUE should  
997 be driven by an increase in the proportion of leaf nitrogen allocated to photosyn-  
998 thetic tissue, a pattern that should allow plants to achieve optimal photosynthetic  
999 rates with greater photosynthetic capacity to make better use of available light.  
1000 Contrasting theory predictions, I found no effect of soil nitrogen availability on  
1001 photosynthetic capacity. However, photosynthetic capacity did tend to increase  
1002 with increasing soil nitrogen availability ( $p<0.20$ ; Table 3.2) resulting in no effect  
1003 of soil nitrogen availability on the relative fraction of leaf nitrogen allocated to  
1004 photosynthesis, Rubisco, or bioenergetics. These lines of evidence support the  
1005 idea that trees use additional nitrogen to support increased leaf nitrogen alloca-  
1006 tion toward photosynthetic tissue and enhance photosynthetic capacity (Wright  
1007 et al. 2003).

1008        Soil nitrogen availability had a stronger effect on leaf nitrogen than photo-  
1009        tosynthetic capacity. This pattern suggests that additional plant nitrogen up-  
1010        take due to increased soil nitrogen availability was also being used to support  
1011        non-photosynthetic nitrogen pools, possibly to structural tissue or stress-induced  
1012        amino acid and polyamine synthesis (Minocha et al. 2000; Onoda et al. 2004;  
1013        Bubier et al. 2011). While I found no change in the proportion of leaf nitrogen  
1014        allocated to leaf structural tissue, the overall stimulation in leaf nitrogen content  
1015        with increasing soil nitrogen availability suggests an increase in the net amount of  
1016        nitrogen invested in leaf structural tissue along the nitrogen availability gradient.  
1017        Importantly, leaf nitrogen allocated to structure was calculated using an empiri-  
1018        cal relationship between  $M_{\text{area}}$  and the amount of leaf nitrogen allocated to cell  
1019        walls (Onoda et al. 2017). As the generality of relationships between  $M_{\text{area}}$  and  
1020        the amount of leaf nitrogen allocated to cell walls has been called into question  
1021        (Harrison et al. 2009), future work should consider explicitly measuring nitrogen  
1022        allocation to cell wall tissue and stress-induced amino acid synthesis to confirm  
1023        these patterns.

1024        In opposition to patterns expected from least-cost theory, increasing soil  
1025        nitrogen availability had no apparent effect on  $\chi$ . Interestingly, despite the null  
1026        effect of soil nitrogen availability on  $\chi$ , I observed a strong negative effect of  
1027        increasing  $N_{\text{area}}$  on  $\chi$ , consistent with the nitrogen-water use tradeoffs expected  
1028        from theory. The null response of  $\chi$  to increasing soil nitrogen availability may  
1029        have been due to a lack of water limitation in the system, given that the area  
1030        received approximately 20% more precipitation (1167 mm) during the 12-month  
1031        period leading up to our measurement period than normally expected (972 mm).

1032 However, droughts can and do occur in temperate forests of the northeastern  
1033 United States (Sweet et al. 2017), so the observed increase in leaf nitrogen content  
1034 with increasing soil nitrogen availability could be a strategy that allows trees to  
1035 hedge bets against drier than normal growing seasons (Onoda et al. 2004; Onoda  
1036 et al. 2017; Hallik et al. 2009). As was suggested in Paillassa et al. (2020),  
1037 and more recently by Querejeta et al. (2022), negative effects of soil nitrogen  
1038 availability on  $\chi$  may increase with increasing aridity. This strategy would be  
1039 especially advantageous if it allows individuals growing in arid regions to maintain  
1040 carbon assimilation rates with reduced water loss. Future work should attempt to  
1041 quantify interactive roles of climate and soil nitrogen availability on nitrogen-water  
1042 use tradeoffs, which could be done using coordinated and multifactor nutrient  
1043 (Borer et al. 2014) and water (Knapp et al. 2017) manipulation experiments  
1044 across broad climatic gradients.

1045 3.4.2 *Soil pH did not modify tradeoffs between nitrogen and water usage*  
1046 While the primary purpose of this study was to examine the role of soil nitrogen  
1047 availability on nitrogen-water use tradeoffs, this experiment manipulated both  
1048 soil nitrogen and pH, thus providing an opportunity to isolate the these variables  
1049 [DWS: example edit]. Previous correlational studies along environmental gradi-  
1050 ents have identified soil pH as a particularly important factor that can modify  
1051 tradeoffs between nutrient and water use (Smith et al. 2019; Paillassa et al. 2020;  
1052 Westerband et al. 2023) and the proportion of leaf nitrogen allocated to photosyn-  
1053 thesis (Luo et al. 2021). Such studies implied that these patterns may be driven  
1054 by reductions in the cost of acquiring nutrients relative to water with increasing

1055 pH, which may be exacerbated in acidic soils.

1056 Consistent with theory (Wright et al. 2003; Prentice et al. 2014), results  
1057 indicate that increasing soil pH was negatively associated with PNUE. However,  
1058 there was no effect of soil pH on leaf nitrogen content,  $\chi$ , or leaf nitrogen content  
1059 per unit  $\chi$ , most likely because the experimental nitrogen additions increased soil  
1060 nitrogen supply while both increasing (sodium nitrate) and decreasing (ammo-  
1061 nium sulfate) soil pH. These results suggest that soil pH did not play a major  
1062 role in modifying expected photosynthetic least-cost theory patterns, contrasting  
1063 findings from Paillassa et al. (2020) and other gradient studies that note positive  
1064 effects of increasing soil pH on leaf nitrogen content, Rubisco carboxylation, and  
1065  $\chi$  (Viet et al. 2013; Cornwell et al. 2018; Luo et al. 2021). Instead, null responses  
1066 to soil pH show that leaf photosynthetic parameters depend more on soil nitrogen  
1067 availability than pH per se, and that inferences from gradient studies might be  
1068 confounding covariation between nitrogen availability and soil acidity.

1069 3.4.3 *Species identity explains a large amount of variation in leaf and whole*  
1070 *plant traits*

1071 Species [species identity?] generally explained a larger amount of variation in  
1072 measured leaf traits than soil nitrogen availability or soil pH. Interspecific vari-  
1073 ation is an important factor to consider when deducing mechanisms that drive  
1074 photosynthetic least-cost theory, particularly for species that form distinct myc-  
1075 orrhizal associations or have different photosynthetic pathways, growth forms, or  
1076 leaf habit (Espelta et al. 2005; Adams et al. 2016; Bialic-Murphy et al. 2021;  
1077 Scott and Smith 2022). The need to consider species may also be important when

**1078** comparing nutrient-water use tradeoffs in early and late successional species, or in  
**1079** species with different resource economic strategies (Abrams and Mostoller 1995;  
**1080** Ellsworth and Reich 1996; Wright et al. 2004; Reich 2014; Onoda et al. 2017;  
**1081** Ziegler et al. 2020).

**1082** [DWS: implications for chapter 2?]

**1083** A strength of the study design and sampling effort is that it controls for  
**1084** many species differences that should modify nitrogen-water use tradeoffs expected  
**1085** from theory. All tree species measured in this study shared the leaf habit of de-  
**1086** ciduous broadleaves, were growing in forests of similar successional stage, but  
**1087** differed in mycorrhizal association and consequent resource economic strategies.  
**1088** As stands tended to be dominated by trees that associate with arbuscular myc-  
**1089** orrhizae (*Fraxinus* and both *Acer* species made up roughly 70% of total above-  
**1090** ground biomass across stands), ecosystem biogeochemical cycle dynamics may be  
**1091** more closely aligned to the inorganic nutrient economy proposed in Phillips et al.  
**1092** (2013), which may promote stronger nitrogen-water use tradeoffs in tree species  
**1093** that associate with arbuscular mycorrhizae. This result was not observed here,  
**1094** as photosynthetic properties varied as much within as across the two mycorrhizal  
**1095** associations represented.

**1096** 3.4.4 *Implications for photosynthetic least-cost theory model development*

**1097** In the field, soil nutrient availability is heterogeneous across time and space (Ta-  
**1098** ble B4). Unaccounted within-plot heterogeneity may have contributed to the low  
**1099** amount of variation explained by soil nitrogen availability in statistical models,  
**1100** as resin bags are a coarse surrogate for soil nitrogen availability. Despite this, I

1101 still observed evidence for nutrient-water use tradeoffs, suggesting that observed  
1102 responses reported here may be an underestimate toward the net effect of soil ni-  
1103 trogen availability on these tradeoffs. While I urge caution in the interpretation of  
1104 these results, they do provide a promising baseline for future studies investigating  
1105 patterns expected from photosynthetic least-cost theory at finer spatiotemporal  
1106 resolutions.

1107 The general stronger relationship between leaf nitrogen content and photo-  
1108 synthetic parameters versus between leaf nitrogen content and soil nitrogen avail-  
1109 ability suggests that leaf nitrogen content is more directly tied to photosynthesis  
1110 than soil nitrogen availability. While this could be due to the high spatiotemporal  
1111 heterogeneity of soil nitrogen availability, principles from photosynthetic least-  
1112 cost theory suggest that leaf nitrogen content is the downstream product of leaf  
1113 nutrient demand to build and maintain photosynthetic machinery, which is set by  
1114 aboveground environmental conditions such as light availability, CO<sub>2</sub>, tempera-  
1115 ture, or vapor pressure deficit (Smith et al. 2019; Paillassa et al. 2020; Peng et al.  
1116 2021; Westerband et al. 2023). The stronger relationship between leaf nitrogen  
1117 and photosynthetic parameters, paired with the strong negative relationship be-  
1118 tween leaf nitrogen and  $\chi$ , could indicate a relatively stronger effect of climate on  
1119 leaf nitrogen-photosynthesis relationships than soil resource availability. However,  
1120 the short distance between plots and across sites limited my ability to test this  
1121 mechanism.

1122 Variation in soil pH affected least cost responses less than variations in soil  
1123 nitrogen availability, in part because experimental treatments directly increased  
1124 soil nitrogen and affected soil pH in opposite directions. While soil pH has been

1125 shown to drive nitrogen-water tradeoffs in global gradient analyses (Viet et al.  
1126 2013; Paillassa et al. 2020), these responses may be due to covariations between  
1127 soil pH and nutrient cycling rather than a role of pH per se. The direct manipula-  
1128 tions of soil pH and soil nitrogen availability in this study partly disentangle these  
1129 factors and show that variation in nitrogen availability matters more for least-cost  
1130 tradeoffs than pH alone.

1131 3.4.5 *Conclusions*

1132 Increasing soil nitrogen availability generally increased leaf nitrogen content (both  
1133 area- and mass-based), but did not significantly influence  $\chi$ . This shift in leaf ni-  
1134 trogen led to a reduction in PNUE, and an increase in leaf nitrogen per unit  
1135  $\chi$  with increasing soil nitrogen availability. Despite null effects of soil nitrogen  
1136 availability on  $\chi$ , I observed a strong negative relationship between leaf nitrogen  
1137 content and  $\chi$ . These results provide empirical support for the nutrient-water use  
1138 tradeoffs expected from photosynthetic least-cost theory in response to increas-  
1139 ing soil nutrient availability, but suggest that all tenets of the theory may not  
1140 hold in every environment. These results experimentally test previous work sug-  
1141 gesting that leaf nitrogen-water economies vary across gradients of soil nutrient  
1142 availability and pH, and show that variations in nutrient availability matter more  
1143 for determining variation in leaf photosynthetic traits than soil pH.

1144

## Chapter 4

1145 The relative cost of resource use for photosynthesis drives variance in  
1146 leaf nitrogen content across a climate and soil resource availability  
1147 gradient

1148 4.1 Introduction

1149 Terrestrial biosphere models, which comprise the land surface component of Earth  
1150 system models, are sensitive to the formulation of photosynthetic processes (Knorr  
1151 and Heimann 2001; Ziehn et al. 2011; Booth et al. 2012; Walker et al. 2021).  
1152 This is because photosynthesis is the largest carbon flux between the atmosphere  
1153 and terrestrial biosphere (IPCC 2021), and is constrained by ecosystem carbon  
1154 and nutrient cycles (Hungate et al. 2003; LeBauer and Treseder 2008; Fay et al.  
1155 2015). Many terrestrial biosphere models formulate photosynthesis by parame-  
1156 terizing photosynthetic capacity within plant functional groups through empiri-  
1157 cal linear relationships between area-based leaf nitrogen content ( $N_{\text{area}}$ ) and the  
1158 maximum carboxylation rate of Ribulose-1,5-bisphosphate carboxylase/oxygenase  
1159 ( $V_{\text{cmax}}$ ) (Kattge et al. 2009; Rogers 2014; Rogers et al. 2017). Models are also  
1160 beginning to include connected carbon-nitrogen cycles (Wieder et al. 2015; Shi  
1161 et al. 2016; Davies-Barnard et al. 2020; Braghieri et al. 2022), which allows leaf  
1162 photosynthesis to be predicted directly through changes in  $N_{\text{area}}$  and indirectly  
1163 through changes in soil nitrogen availability (e.g., LPJ-GUESS, CLM5.0) (Smith  
1164 et al. 2014; Lawrence et al. 2019). Despite recent model developments, open  
1165 questions remain regarding the generality of ecological relationships between soil  
1166 nitrogen availability, leaf nitrogen content, and leaf photosynthesis across edaphic  
1167 and climatic gradients.

1168 Empirical support for positive relationships between soil nitrogen availabil-  
1169 ity and  $N_{\text{area}}$  is abundant (Firn et al. 2019; Liang et al. 2020), and is a result  
1170 often attributed to the high nitrogen cost of building and maintaining Rubisco  
1171 (Evans 1989; Evans and Seemann 1989; Onoda et al. 2004; Walker et al. 2014;  
1172 Onoda et al. 2017; Dong et al. 2020). Such patterns imply that positive relation-  
1173 ships between soil nitrogen availability and  $N_{\text{area}}$  should increase leaf photosyn-  
1174 thesis and photosynthetic capacity by increasing the maximum rate of Rubisco  
1175 carboxylation through increased investments to Rubisco construction and mainte-  
1176 nance. This integrated  $N_{\text{area}}$ -photosynthesis response to soil nitrogen availability  
1177 has been observed both in manipulative experiments and across environmental  
1178 gradients (Field and Mooney 1986; Evans 1989; Walker et al. 2014; Li et al.  
1179 2020), and is thought to be driven by ecosystem nitrogen limitation, which lim-  
1180 its primary productivity globally (LeBauer and Treseder 2008; Fay et al. 2015).  
1181 However, this response is not consistently observed, as recent studies note variable  
1182  $N_{\text{area}}$ -photosynthesis relationships across edaphic and climatic gradients (Liang  
1183 et al. 2020; Luo et al. 2021) and that aboveground growing conditions (e.g., light  
1184 availability, temperature, vapor pressure deficit) or species identity traits (e.g.,  
1185 photosynthetic pathway, nitrogen acquisition strategy) may be more important  
1186 for explaining variance in  $N_{\text{area}}$  and photosynthetic capacity across environmental  
1187 gradients (Adams et al. 2016; Dong et al. 2017; Smith et al. 2019; Dong et al.  
1188 2020; Peng et al. 2021; Dong et al. 2022; Westerband et al. 2023).

1189 One hypothesized mechanism to explain variance in  $N_{\text{area}}$  across environ-  
1190 mental gradients has been proposed via photosynthetic least-cost theory (Wright  
1191 et al. 2003; Prentice et al. 2014; Paillassa et al. 2020; Harrison et al. 2021).

**1192** The theory predicts that plants acclimate to environments by optimizing photo-  
**1193** synthetic assimilation rates at the lowest summed cost of nitrogen and water use  
**1194** (Wright et al. 2003; Prentice et al. 2014). In a given environment, the theory  
**1195** suggests that nitrogen and water use can be substituted for each other to maintain  
**1196** the lowest summed cost of resource use, such that optimal photosynthetic rates  
**1197** are achieved with less efficient use of the more abundant and less costly resource  
**1198** to acquire in exchange for more efficient use of the less abundant and more costly  
**1199** resource to acquire.

**1200** Photosynthetic least-cost theory predicts that, all else equal, an increase in  
**1201** soil nitrogen availability should decrease the cost of acquiring and using nitrogen  
**1202** relative to water (a ratio referred to herein as  $\beta$ ), resulting in optimal photosyn-  
**1203** thetic rates achieved with greater  $N_{\text{area}}$  at lower stomatal conductance and lower  
**1204** leaf  $C_i:C_a$  (Wright et al. 2003; Prentice et al. 2014; Paillassa et al. 2020). Alter-  
**1205** natively, an increase in soil moisture should reduce costs of water acquisition and  
**1206** use, increasing  $\beta$  (Lavergne et al. 2020), stomatal conductance, and leaf  $C_i:C_a$ , re-  
**1207** sulting in optimal photosynthetic rates achieved with decreased  $N_{\text{area}}$ . The theory  
**1208** also predicts variability in stomatal conductance and  $N_{\text{area}}$  in response to climatic  
**1209** factors, suggesting that the optimal response to increased vapor pressure deficit  
**1210** should be a reduction in stomatal conductance and leaf  $C_i:C_a$  that is counter-  
**1211** balanced by an increase in  $N_{\text{area}}$  to support the greater photosynthetic capacity  
**1212** needed to maintain high assimilation at lower conductance (Grossiord et al. 2020;  
**1213** Dong et al. 2020; López et al. 2021; Westerband et al. 2023).

**1214** Leaf nitrogen allocation responses to changing climates or soil resource  
**1215** availability may also depend on their mode of nutrient acquisition or photo-

1216 synthetic pathway. For example, species that form associations with symbiotic  
1217 nitrogen-fixing bacteria (referred as “N-fixing species” from this point forward)  
1218 should, in theory, have access to less finite nitrogen supply than species not capa-  
1219 ble of forming such associations (referred as “non-fixing species” from this point  
1220 forward), which may result in lower  $\beta$  values in N-fixing species than non-fixing  
1221 species. This result was previously shown in a greenhouse experiment, where a  
1222 leguminous species generally had lower costs of nitrogen acquisition compared to a  
1223 non-leguminous species, although these differences were generally stronger under  
1224 increased nitrogen limitation (Perkowski et al. 2021). Lower  $\beta$  values could be an  
1225 explanation for why N-fixing species commonly have greater leaf nitrogen content  
1226 than non-fixing species (Adams et al. 2016; Dong et al. 2017).

1227 Similarly, leaf nitrogen allocation patterns across environmental gradients  
1228 may be dependent on photosynthetic pathway. Lower leaf  $C_i:C_a$  values in C<sub>4</sub>  
1229 species suggests that C<sub>4</sub> species should have lower  $\beta$  values than C<sub>3</sub> species (Scott  
1230 and Smith 2022), a pattern that could be the result of increased costs associated  
1231 with water acquisition and use or reduced costs of nitrogen acquisition and use  
1232 relative to C<sub>3</sub> species. Theory predicts that this response in C<sub>4</sub> species will cause  
1233 C<sub>4</sub> species to have higher leaf nitrogen content on average compared to C<sub>3</sub> species,  
1234 though ample evidence exists documenting general lower leaf nitrogen content in  
1235 C<sub>4</sub> species (Schmitt and Edwards 1981; Sage and Pearcy 1987; Ghannoum et al.  
1236 2011). No study to date has directly quantified  $\beta$  in C<sub>4</sub> species aside from the  
1237 initial parameterization of  $\beta$  in an optimality model for C<sub>4</sub> species (Scott and  
1238 Smith 2022) using a global dataset of leaf  $\delta^{13}\text{C}$  values (Cornwell et al. 2018).

1239 While photosynthetic least-cost theory provides a unified framework for

1240 understanding integrated effects of climate and soil resource availability on  $N_{\text{area}}$ ,  
1241 empirical tests of the theory are sparse. Previous work shows that increasing  
1242 soil nitrogen availability decreases costs of acquiring nutrients (Bae et al. 2015;  
1243 Perkowski et al. 2021; Lu et al. 2022), which can induce predictable nutrient-  
1244 water use tradeoffs expected from the theory across broad environmental gradients  
1245 (Paillassa et al. 2020; Querejeta et al. 2022; Westerband et al. 2023) and in  
1246 manipulation experiments (Bialic-Murphy et al. 2021). Additionally, increasing  
1247 vapor pressure deficit has been shown to have a positive effect on  $N_{\text{area}}$ , which is  
1248 commonly associated with reduced leaf  $C_i:C_a$  (Dong et al. 2017; Dong et al. 2020;  
1249 Firn et al. 2019; López et al. 2021).

1250 Despite evidence for patterns expected from photosynthetic least-cost the-  
1251 ory, studies have been restricted to exploring these patterns in C<sub>3</sub> species and,  
1252 while variance in  $N_{\text{area}}$  across environmental gradients has been shown to be driven  
1253 by strong negative relationships with leaf  $C_i:C_a$  (Dong et al. 2017; Paillassa et al.  
1254 2020; Westerband et al. 2023), no study has explicitly investigated effects of soil  
1255 resource availability or species identity on  $N_{\text{area}}$  using  $\beta$  as a direct predictor of  
1256 leaf  $C_i:C_a$ . Furthermore, as  $N_{\text{area}}$  can be broken down into structural (leaf mass  
1257 per area;  $M_{\text{area}}$ ; g m<sup>-2</sup>) and metabolic (mass-based leaf nitrogen content;  $N_{\text{mass}}$ ;  
1258 gN g<sup>-1</sup>) components (Dong et al. 2017), no study has investigated which compo-  
1259 nent of  $N_{\text{area}}$  drives the hypothesized response of  $N_{\text{area}}$  to leaf  $C_i:C_a$ , which limits  
1260 our ability to assess whether changes in  $N_{\text{area}}$  across environmental gradients are  
1261 driven by changes in leaf morphology (i.e.  $M_{\text{area}}$ ), leaf stoichiometry (i.e.  $N_{\text{mass}}$ ),  
1262 or both.

1263 In this study, I measured  $N_{\text{area}}$ ,  $N_{\text{mass}}$ ,  $M_{\text{area}}$ , leaf  $\delta^{13}\text{C}$ -derived estimates

1264 of leaf  $C_i:C_a$ , and leaf  $\delta^{13}\text{C}$ -derived estimates of  $\beta$  in 504 individuals spanning  
1265 52 species scattered across 24 grassland sites in Texas, USA. The state of Texas  
1266 contains a diverse climatic gradient, indicated by 2006-2020 mean annual precipi-  
1267 tation totals ranging from 204 to 1803 mm and 2006-2020 mean annual tempera-  
1268 ture ranging from  $11.8^\circ$  to  $24.6^\circ\text{C}$  within state boundaries (Fig. 4.1). Variability  
1269 in soil nitrogen availability and soil moisture was expected across sites, owing to  
1270 differences in soil texture and aboveground climate that would drive differential  
1271 rates of water retention and nitrogen transformations to plant-available nitrogen  
1272 substrate. I leveraged the expected climatic and soil resource variability across  
1273 sites to test the following hypotheses:

- 1274 1. Soil nitrogen availability will decrease  $\beta$  through a reduction in costs of  
1275 nitrogen acquisition and use, while soil moisture will increase  $\beta$  through a  
1276 reduction in costs of water acquisition and use. Following previous results, I  
1277 expected that N-fixing species would have lower  $\beta$  values and that  $C_4$  species  
1278 would have lower  $\beta$  values.
- 1279 2. Leaf  $C_i:C_a$  will be positively related to  $\beta$ , a pattern that will result in a  
1280 negative indirect effect of increasing soil nitrogen availability on leaf  $C_i:C_a$ ,  
1281 a positive indirect effect of increasing soil moisture on leaf  $C_i:C_a$ , and lower  
1282 leaf  $C_i:C_a$  in both N-fixing species and  $C_4$  species. I expected that leaf  
1283  $C_i:C_a$  would be negatively related to vapor pressure deficit, as increasing  
1284 atmospheric dryness would cause plants to close stomata to minimize water  
1285 loss.
- 1286 3.  $N_{\text{area}}$  will be negatively related to leaf  $C_i:C_a$ . This response will result in an  
1287 indirect positive and negative effect of increasing soil nitrogen availability

1288 and soil moisture, respectively, on  $N_{\text{area}}$ , and larger  $N_{\text{area}}$  values in N-fixing  
1289 species. While theory predicts that lower  $\beta$  values in C<sub>4</sub> species should  
1290 yield larger  $N_{\text{area}}$  in C<sub>4</sub> species, I expected that C<sub>4</sub> species would have lower  
1291  $N_{\text{area}}$  than C<sub>3</sub> species due to greater nitrogen use efficiency in C<sub>4</sub> species.  
1292 Additionally, I expected vapor pressure deficit to increase  $N_{\text{area}}$ , a pattern  
1293 that would be directly mediated through the reduction in leaf  $C_i:C_a$  with  
1294 increasing vapor pressure deficit.

1295 4.2 Methods

1296 4.2.1 *Site descriptions and sampling methodology*

1297 Leaf and soil samples were collected from 24 open canopy grassland sites scattered  
1298 across central and eastern Texas in summer 2020 and summer 2021 (Fig. 4.1).  
1299 Twelve sites were visited between June and July 2020 and 14 sites (11 unique from  
1300 2020) were visited between May and June 2021 (Table 4.1). Sites were chosen to  
1301 maximize precipitation and edaphic variability across sites (Table 4.1). No site  
1302 with personally communicated or anecdotal evidence of grazing or disturbance  
1303 (e.g., mowing, feral hog activity, etc.) was used. Leaf material was collected  
1304 from three individuals each of the five most abundant species at random locations  
1305 at each site, only selecting species that were broadly classified as graminoid or  
1306 forb/herb growth habits per the USDA PLANTS database (USDA NRCS 2022).  
1307 All collected leaves were fully expanded with no visible herbivory or other external  
1308 damage and also free from shading by nearby shrubs or trees. Five soil samples  
1309 were collected from 0-15 cm below the soil surface at each site near the leaf  
1310 collection sample locations. Soil samples were mixed together by hand to create

**1311** one composite soil sample per site.

**1312** 4.2.2 *Leaf trait measurements*

**1313** Images of each leaf were taken immediately following each site visit using a flat-

**1314** bed scanner. Fresh leaf area was determined from each image using the ‘LeafArea’

**1315** R package (Katabuchi 2015), which automates leaf area calculations using ImageJ

**1316** software (Schneider et al. 2012). Each leaf was dried at 65°C for at least 48 hours

**1317** to a constant mass, weighed, and manually ground in a mortar and pestle until

**1318** homogenized. Leaf mass per area ( $M_{\text{area}}$ ; g m<sup>-2</sup>) was calculated as the ratio of

**1319** dry leaf biomass to fresh leaf area. Subsamples of dried and homogenized leaf

**1320** tissue were used to measure leaf nitrogen content ( $N_{\text{mass}}$ ; gN g<sup>-1</sup>) through ele-

**1321** mental combustion analysis (Costech-4010, Costech Instruments, Valencia, CA).

**1322** Leaf nitrogen content per unit leaf area ( $N_{\text{area}}$ ; gN m<sup>-2</sup>) was calculated as the

**1323** product of  $N_{\text{mass}}$  and  $M_{\text{area}}$ .

**1324** Subsamples of dried and homogenized leaf tissue were sent to the University

**1325** of California-Davis Stable Isotope Facility to determine leaf  $\delta^{13}\text{C}$ . Leaf  $\delta^{13}\text{C}$  values

**1326** were determined using an elemental analyzer (PDZ Europa ANCA-GSL; Sercon

**1327** Ltd., Chestshire, UK) interfaced to an isotope ratio mass spectrometer (PDZ

**1328** Europa 20-20 Isotope Ratio Mass Spectrometer, Sercon Ltd., Chestshire, UK).

**1329** I used leaf  $\delta^{13}\text{C}$  values (‰; relative to Vienna Pee Dee Belemnite international

**1330** reference standard) to estimate the ratio of intercellular ( $C_i$ ) to extracellular ( $C_a$ )

**1331** CO<sub>2</sub> ratio (leaf  $C_i:C_a$ ; unitless) following the approach of Farquhar et al. (1989)

**1332** described in Cernusak et al. (2013). Specifically, I derived leaf  $C_i:C_a$  as:

$$C_i : C_a = \frac{\Delta^{13}C - a}{b - a} \quad (4.1)$$

**1333** where  $\Delta^{13}C$  represents the relative difference between leaf  $\delta^{13}\text{C}$  ( $\text{\textperthousand}$ ) and air  $\delta^{13}\text{C}$

**1334** ( $\text{\textperthousand}$ ), calculated as:

$$\Delta^{13}C = \frac{\delta^{13}C_{air} - \delta^{13}C_{leaf}}{1 + \delta^{13}C_{leaf}} \quad (4.2)$$

**1335**  $\delta^{13}\text{C}_{air}$ , which is commonly assumed to be  $-8\text{\textperthousand}$  (Keeling et al. 1979; Farquhar

**1336** et al. 1989), was calculated as a function of calendar year  $t$  using an empirical

**1337** equation derived in Feng (1999):

$$\delta^{13}C_{air} = -6.429 - 0.006e^{0.0217(t-1740)} \quad (4.3)$$

**1338** Using this equation,  $\delta^{13}\text{C}_{air}$  values were set to  $-9.04\text{\textperthousand}$  and  $-9.09\text{\textperthousand}$  for 2020 and

**1339** 2021, respectively. The parameter  $a$  represents the fractionation between  $^{12}\text{C}$

**1340** and  $^{13}\text{C}$  due to diffusion in air, assumed to be  $4.4\text{\textperthousand}$ , while  $b$  represents the

**1341** fractionation caused by Rubisco carboxylation, assumed to be  $27\text{\textperthousand}$  (Farquhar

**1342** et al. 1989). For  $\text{C}_4$  species,  $b$  in Eqn. 4.1 was set to  $6.3\text{\textperthousand}$ , and was derived from:

$$b = c + (d \cdot \phi) \quad (4.4)$$

**1343** Where  $c$  was set to  $-5.7\text{\textperthousand}$  and  $d$  was set to  $30\text{\textperthousand}$  (Farquhar et al. 1989).  $\phi$ , which

**1344** is the bundle sheath leakiness term, was set to 0.4. All leaf  $C_i:C_a$  values less than

**1345** 0.1 and greater than 0.95 were assumed to be incorrect and removed from the

**1346** analysis.

**1347** I derived the unit cost of resource use ( $\beta$ ) using leaf  $C_i:C_a$  and site climate

**1348** data using equations first described in Prentice et al. (2014) and simplified in

**1349** Lavergne et al. (2020):

$$\beta = 1.6\eta^*VPD \frac{\chi - (\frac{\Gamma^*}{C_a})^2}{(1 - \chi)^2(K_m + \Gamma^*)} \quad (4.5)$$

**1350** where  $\eta^*$  is the viscosity of water relative to 25°C, calculated using elevation and

**1351** mean air temperature of the seven days leading up to each site visit following equa-

**1352** tions in Huber et al. (2009). VPD (Pa) was set to the mean vapor pressure deficit

**1353** of the seven days leading up to each site visit,  $C_a$  represents atmospheric CO<sub>2</sub>

**1354** concentration, arbitrarily set to 420 μmol mol<sup>-1</sup> CO<sub>2</sub>.  $K_m$  (Pa) is the Michaelis-

**1355** Menten coefficient for Rubisco affinity to CO<sub>2</sub> and O<sub>2</sub>, calculated as:

$$K_m = K_c \cdot \left(1 + \frac{O_i}{K_o}\right) \quad (4.6)$$

**1356** where  $K_c$  (Pa) and  $K_o$  (Pa) are the Michaelis-Menten coefficients for Rubisco

**1357** affinity to CO<sub>2</sub> and O<sub>2</sub>, respectively, and  $O_i$  is the intercellular O<sub>2</sub> concentration.

**1358**  $\Gamma^*$  (Pa) is the CO<sub>2</sub> compensation point in the absence of dark respiration.  $K_c$ ,  $K_o$ ,

**1359** and  $\Gamma^*$  were determined using equations described in Medlyn et al. (2002) and

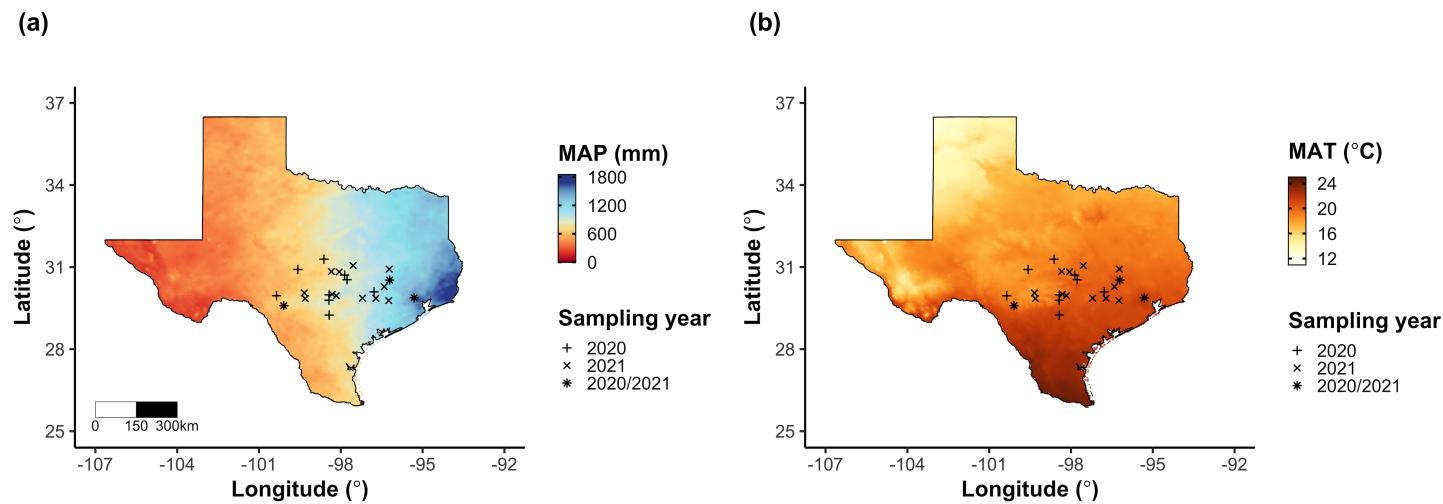

**1360** derived in Bernacchi et al. (2001), invoking an elevation correction for atmospheric

**1361** pressure as explained in Stocker et al. (2020).

**Table 4.1.** Site locality information, sampling year, 2006-2020 mean annual precipitation (MAP; mm), mean annual temperature (MAT; °C), and water holding capacity (WHC; mm)\*

**1362** \* Rows are arranged by longitude to visualize precipitation variability across sites

**Figure 4.1.** Site locations along 2006-2020 mean annual precipitation (a) and mean annual temperature (b) gradients in Texas, USA. Precipitation and temperature data were plotted using PRISM data at a 4-km grid resolution and are masked to include only grid cells that occur within the Texas state boundary of the United States. In both panels, addition signs refer to sites visited in 2020, multiplication signs to sites visited in 2021, and asterisks to sites visited in 2020 and 2021. The scale bar in (a) also applies to (b).

**1363** 4.2.3 *Site climate data*

**1364** I used the Parameter elevation Regressions on Independent Slopes Model (PRISM)  
**1365** (Daly et al. 2008) climate product to access gridded daily temperature and precip-  
**1366** itation data for the coterminous United States at a 4-km grid resolution between  
**1367** January 1, 2006 and July 31, 2021 (PRISM Climate Group, Oregon State Uni-  
**1368** versity, <https://prism.oregonstate.edu>, data created 4 Feb 2014, accessed 24  
**1369** Mar 2022). Mean daily air temperature, mean daily vapor pressure deficit, and  
**1370** total daily precipitation data were extracted from the grid cell that contained the  
**1371** latitude and longitude of each property using the ‘extract’ function in the ‘terra’  
**1372** R package (Hijmans 2022). PRISM data were used in lieu of local weather sta-  
**1373** tion data because several rural sites did not have a local weather station present  
**1374** within a 20-km radius of the site. Daily site climate data were used to estimate  
**1375** mean annual precipitation and mean annual temperature for each site between  
**1376** 2006 and 2020 (Table 4.1). I calculated total precipitation and mean daily vapor  
**1377** pressure deficit for the prior 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 15, 20, 25, 30, 60, and 90  
**1378** days leading up to each site visit. Temperature was not included in any analy-  
**1379** sis due to the close range in mean annual temperature between sites (mean±SD:  
**1380**  $19.8 \pm 0.9^\circ\text{C}$ ; Table 4.1).

**1381** 4.2.4 *Site edaphic characteristics*

**1382** Composted soil samples were sent to the Texas A&M Soil, Water and Forage  
**1383** Laboratory to quantify soil nitrate concentration ( $\text{NO}_3\text{-N}$ ; ppm). Soil  $\text{NO}_3\text{-N}$   
**1384** was determined by extracting composite soil samples in 1 M KCl, measuring  
**1385** absorbance values of extracts at 520 nm using the end product of a  $\text{NO}_3\text{-N}$  to

**1386** NO<sub>2</sub>-N cadmium reduction reaction (Kachurina et al. 2000; Keeney and Nelson  
**1387** 1983). Soil texture data from 0-15 cm below the soil surface were accessed using  
**1388** the SoilGrids2.0 data product (Poggio et al. 2021) through the ‘fetchSoilGrids’  
**1389** function in the ‘soilDB’ R package (Beaudette et al. 2022). I used SoilGrids2.0  
**1390** to access soil texture data in lieu of analyses using the composite soil sample due  
**1391** to a lack of soil material from some sites after sending samples for soil NO<sub>3</sub>-N.

**1392** Soil moisture was not measured in the field, but was estimated using the  
**1393** ‘Simple Process-Led Algorithms for Simulating Habitats’ model (SPLASH) (Davis  
**1394** et al. 2017). This model, derived from the STASH model (Cramer and Prentice  
**1395** 1988), spins up a bucket model using Priestley-Taylor equations (Priestley and  
**1396** Taylor 1972) to calculate daily soil moisture ( $W_n$ ; mm) as a function of the previous  
**1397** day’s soil moisture ( $W_{n-1}$ ; mm), daily precipitation ( $P_n$ ; mm), condensation ( $C_n$ ;  
**1398** mm), actual evapotranspiration ( $E_n^a$ ; mm), and runoff (RO; mm):

$$W_n = W_{n-1} + P_n + C_n - E_n^a - RO \quad (4.7)$$

**1399** Models were spun up by equilibrating the previous day’s soil moisture using succes-  
**1400** sive model iterations with daily mean air temperature, daily precipitation total,  
**1401** the number of daily sunlight hours, and latitude as model inputs (Davis et al.  
**1402** 2017). Daily sunlight hours were estimated for each day at each site using the  
**1403** ‘getSunlightTimes’ function in the ‘suncalc’ R package, which estimated sunrise  
**1404** and sunset times of each property using date and site coordinates (Thieurmel and  
**1405** Elmarhraoui 2019). Water holding capacity (mm), or bucket size, was estimated  
**1406** as a function of soil texture using pedotransfer equations explained in Saxton and

1407 Rawls (2006), as done in Stocker et al. (2020) and Bloomfield et al. (2023). A  
1408 summary of these equations is included in Appendix C.1.

1409 Daily soil moisture outputs from the SPLASH model for each site were  
1410 used to calculate mean daily soil moisture for the prior 1, 2, 3, 4, 5, 6, 7, 8, 9,  
1411 10, 15, 20, 25, 30, 60, and 90 days leading up to each site visit. Mean daily  
1412 soil moisture values were then expressed as a fraction of water holding capacity  
1413 to normalize across sites with different bucket depths, as done in Stocker et al.  
1414 (2018). Site water holding capacity values are referenced in Table 4.1.

1415 4.2.5 *Plant functional group assignments*

1416 Plant functional group was assigned to each species and used as the primary de-  
1417 scriptor of species identity. Specifically, plant functional groups were assigned  
1418 based on photosynthetic pathway ( $C_3$ ,  $C_4$ ) and ability to form associations with  
1419 symbiotic nitrogen-fixing bacteria (N-fixer, non-fixer). The ability to form asso-  
1420 ciations with symbiotic nitrogen-fixing bacteria was assigned based on whether  
1421 species were in the *Fabaceae* family, and photosynthetic pathway of each species  
1422 was determined from past literature and confirmed through leaf  $\delta^{13}C$  values. I  
1423 chose these plant functional groups based on *a priori* hypotheses regarding the  
1424 functional role of nitrogen fixation and photosynthetic pathway on the sensitivity  
1425 of plant nitrogen uptake and leaf nitrogen allocation to soil nitrogen availability  
1426 and aboveground growing conditions. These plant functional group classifications  
1427 resulted in three distinct plant functional groups within our dataset:  $C_3$  N-fixers  
1428 (n=53),  $C_3$  non-fixers (n=334), and  $C_4$  non-fixers (n=117).

**1429** 4.2.6 *Data analysis*

**1430** All analyses and plotting were conducted in R version 4.1.1 (R Core Team 2021).

**1431** I constructed a series of separate linear mixed-effects models to investigate en-

**1432** vironmental drivers of  $\beta$ , leaf  $C_i:C_a$ ,  $N_{\text{area}}$ ,  $N_{\text{mass}}$ , and  $M_{\text{area}}$ , followed by a path

**1433** analysis using a piecewise structural equation model to investigate direct and

**1434** indirect effects of climate and soil resource availability on  $N_{\text{area}}$ .

**1435** To explore environmental drivers of  $\beta$ , I built a linear mixed-effects model

**1436** that included soil moisture, soil nitrogen availability, and plant functional group

**1437** as fixed effect coefficients. Species were designated as a random intercept term.

**1438** Interaction coefficients between all possible combinations of the three fixed effect

**1439** coefficients were also included.  $\beta$  was natural log transformed to linearize data.

**1440** I used an information-theoretic model selection approach to determine whether

**1441** 90-, 60-, 30-, 20-, 15-, 10-, 9-, 8-, 7-, 6-, 5-, 4-, 3-, 2-, or 1-day mean daily soil

**1442** moisture conferred the best model fit for  $\beta$ . To do this, I constructed 16 separate

**1443** linear mixed-effects models where log-transformed  $\beta$  was included as the response

**1444** variable and each soil moisture time step was separately included as a single

**1445** continuous fixed effect. Species were included as a random intercept term for all

**1446** models. I used corrected Akaike Information Criterion (AICc) to select the soil

**1447** moisture timescale that conferred the best model fit, indicated by the model with

**1448** the lowest AICc score (Table C3; Fig. C1).

**1449** To explore environmental drivers of leaf  $C_i:C_a$ , I constructed a second lin-

**1450** ear mixed effects model that included vapor pressure deficit, soil moisture, soil

**1451** nitrogen availability, and plant functional group as fixed effect coefficients. Two-

**1452** way interactions between plant functional group and vapor pressure deficit, soil

1453 nitrogen availability, or soil moisture were included as additional fixed effect coef-  
1454 ficients, in addition to a three-way interaction between soil moisture, soil nitrogen  
1455 availability, and plant functional group. Species were included as a random inter-  
1456 cept term. I used an information-theoretic model selection approach to determine  
1457 whether 90-, 60-, 30-, 20-, 15-, 10-, 9-, 8-, 7-, 6-, 5-, 4-, 3-, 2-, or 1-day mean daily  
1458 vapor pressure deficit conferred the best model fit for leaf  $C_i:C_a$  using the same  
1459 approach explained above for the soil moisture effect on  $\beta$ . The soil moisture  
1460 timescale was set to the same timescale that conferred the best fit for  $\beta$ .

1461 To explore environmental drivers of  $N_{\text{area}}$ ,  $N_{\text{mass}}$ , and  $M_{\text{area}}$ , I constructed  
1462 a linear mixed effects model for each trait, including leaf  $C_i:C_a$ , soil nitrogen  
1463 availability, soil moisture, and plant functional group as fixed effect coefficients  
1464 for each model. Two-way interactions between plant functional group and  $\beta$ , leaf  
1465  $C_i:C_a$ , soil nitrogen availability, or soil moisture were included as additional fixed  
1466 effect coefficients, in addition to a three-way interaction between soil nitrogen  
1467 availability, soil moisture, and plant functional group. Species were included as a  
1468 random intercept term, with the soil moisture timescale set to the same timescale  
1469 that conferred the best fit for  $\beta$ .

1470 In all linear mixed-effects models explained above, including those to select  
1471 relevant timescales, I used the ‘lmer’ function in the ‘lme4’ R package (Bates et al.  
1472 2015) to fit each model and the ‘Anova’ function in the ‘car’ R package (Fox and  
1473 Weisberg 2019) to calculate Type II Wald’s  $\chi^2$  and determine the significance  
1474 level ( $\alpha=0.05$ ) of each fixed effect coefficient. I used the ‘emmeans’ R package  
1475 (Lenth 2019) to conduct post-hoc comparisons using Tukey’s tests, where degrees  
1476 of freedom were approximated using the Kenward-Roger approach (Kenward and

1477 Roger 1997). Trendlines and error ribbons for all plots were drawn using a series  
1478 of ‘emmeans’ outputs across the range in plotted x-axis values.

1479 Finally, I conducted a path analysis using a piecewise structural equation  
1480 model to examine direct and indirect pathways that determined variance in  $N_{\text{area}}$ .  
1481 Six separate linear mixed effects models were loaded into the piecewise structural  
1482 equation model. Models were constructed per *a priori* hypotheses following pat-  
1483 terns expected from photosynthetic least-cost theory. The first model regressed  
1484  $N_{\text{area}}$  against  $N_{\text{mass}}$  and  $M_{\text{area}}$ . The second model regressed  $M_{\text{area}}$  against leaf  
1485  $C_i:C_a$  and soil nitrogen availability. The third model regressed  $N_{\text{mass}}$  against  
1486 leaf  $C_i:C_a$  and  $M_{\text{area}}$  (Dong et al. 2017; Dong et al. 2020). The fourth model re-  
1487 gressed leaf  $C_i:C_a$  against  $\beta$  and vapor pressure deficit. The fifth model regressed  $\beta$   
1488 against soil nitrogen availability, soil moisture, ability to associate with symbiotic  
1489 nitrogen-fixing bacteria, and photosynthetic pathway. The sixth model regressed  
1490 soil nitrogen availability against soil moisture. All models included the relevant  
1491 timescale selected in the individual linear mixed effect models explained above.  
1492 Models included species as a random intercept term, were built using the ‘lme’  
1493 function in the ‘nlme’ R package (Pinheiro and Bates 2022), and subsequently  
1494 loaded into the piecewise structural equation model using the ‘psem’ function in  
1495 the ‘piecewiseSEM’ R package (Lefcheck 2016).

**1496** 4.3 Results

**1497** 4.3.1 *Cost to acquire nitrogen relative to water*

**1498** Model selection indicated that 90-day mean soil moisture conferred the best model

**1499** fit for  $\beta$  (AICc=1387.54; Table C3; Fig. C1).

**1500** Increasing soil nitrogen availability generally decreased  $\beta$  ( $p<0.001$ ; Table

**1501** 4.2; Fig. 4.2a), a pattern driven by a negative effect of increasing soil nitrogen on  $\beta$

**1502** in C<sub>3</sub> non-fixers (Tukey:  $p=0.005$ ) and C<sub>3</sub> N-fixers (Tukey:  $p=0.035$ ) despite a null

**1503** effect of increasing soil nitrogen on  $\beta$  in C<sub>4</sub> non-fixers (Tukey:  $p=0.856$ ). There

**1504** was no effect of soil moisture on  $\beta$  ( $p=0.872$ ; Table 4.2; Fig. 4.2b). A functional

**1505** group effect ( $p<0.001$ ; Table 4.2) indicated that C<sub>4</sub> non-fixers generally had lower

**1506**  $\beta$  values than both C<sub>3</sub> N-fixers and C<sub>3</sub> non-fixers (Tukey:  $p<0.001$  in both cases),

**1507** while  $\beta$  values in C<sub>3</sub> N-fixers did not differ from C<sub>3</sub> non-fixers (Tukey:  $p=0.854$ ).

**1513** copied from a graphing calculator output]

**Figure 4.2.** Effects of soil nitrogen availability (a) and soil moisture (b) on the cost of acquiring and using nitrogen ( $\beta$ ; unitless). Soil nitrogen availability is represented on the x-axis in (a), soil moisture is represented on the x-axis in (b) as a percent of site water holding capacity, and natural-log transformed  $\beta$  is represented on the y-axis for both panels. Yellow points represent  $C_3$  N-fixers, blue points represent  $C_3$  non-fixers, and red points represent  $C_4$  non-fixers. Throughout, points are jittered for visibility. A black solid trendline is drawn to denote bivariate relationships where the slope is different from zero ( $p < 0.05$ ), with error ribbons representing the upper and lower 95% confidence intervals.

**1514** 4.3.2 *Leaf C<sub>i</sub>:C<sub>a</sub>*

**1515** Model selection indicated that 4-day mean vapor pressure deficit was the timescale

**1516** that conferred the best model fit for leaf  $C_i:C_a$  (AICc=-755.81; Table C3; Fig. C1).

**1517** Model results revealed that increasing vapor pressure deficit generally de-

**1518** creased leaf  $C_i:C_a$  ( $p<0.001$ ; Table 4.3; Fig. 4.3a). There was no effect of soil mois-

**1519** ture ( $p=0.549$ ; Table 4.3; Fig. 4.3b) or soil nitrogen availability ( $p=0.549$ ; Table

**1520** 4.3; Fig. 4.3c) on leaf  $C_i:C_a$ . A strong plant functional group effect ( $p<0.001$ ; Ta-

**1521** ble 4.3) indicated that C<sub>4</sub> non-fixers had lower leaf  $C_i:C_a$  than C<sub>3</sub> N-fixers and C<sub>3</sub>

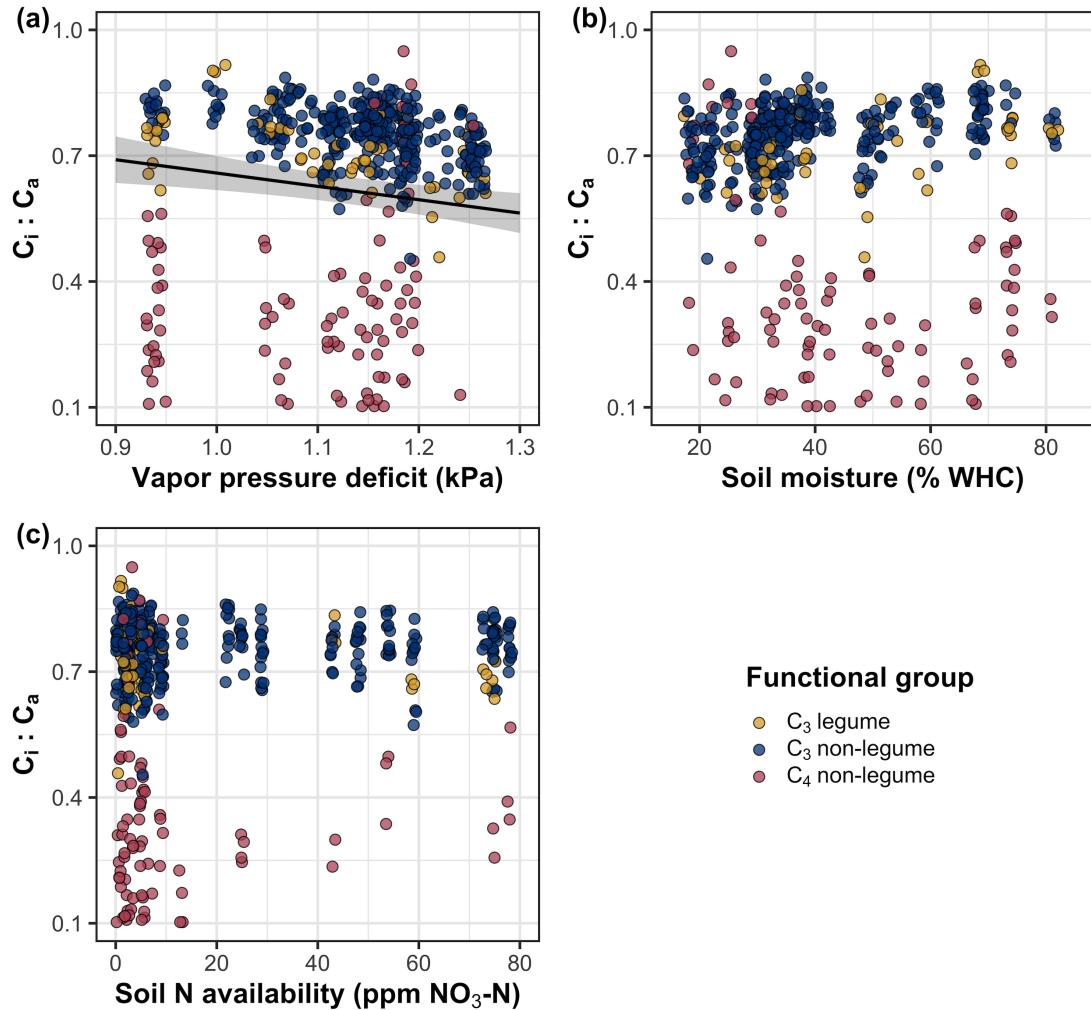

**1522** non-fixers (Tukey:  $p<0.001$  in both cases), with no difference between C<sub>3</sub> N-fixers

**1523** and C<sub>3</sub> non-fixers (Tukey:  $p=0.866$ ).

**Table 4.3.** Effects of soil moisture, soil nitrogen availability, and plant functional group on leaf  $C_i:C_a$  (unitless)\*

**1524** \*Significance determined using Type II Wald  $\chi^2$  tests ( $\alpha=0.05$ ). P-values less  
**1525** than 0.05 are in bold and p-values where  $0.05 < p < 0.1$  are italicized. Leaf  $C_i:C_a$   
**1526** was not transformed prior to model fitting, so model coefficients are reported  
**1527** on the response scale. Model coefficients are only included for continuous fixed  
**1528** effects. Key: df=degrees of freedom;  $\chi^2$ =Wald Type II chi-square test statistic

**Figure 4.3.** Effects of 4-day mean vapor pressure deficit (a), 90-day soil moisture (per water holding capacity; b), and soil nitrogen availability (c) on leaf  $C_i:C_a$ . Shading and trendlines are as explained in Figure 4.2. Points are jittered for visibility. Variably colored trendlines are only included if there is an interaction between the x-axis and plant functional group, where solid trendlines indicate slopes that are different from zero ( $p < 0.05$ ) and dashed trendlines indicate slopes that are not different from zero ( $p > 0.05$ ). Error ribbons represent the upper and lower 95% confidence intervals of each fitted trendline.

**1529** 4.3.3 *Leaf nitrogen content*

**1530** An interaction between leaf  $C_i:C_a$  and plant functional group ( $p<0.001$ ; Table  
**1531** 4.4) revealed that the negative effect of increasing leaf  $C_i:C_a$  on  $N_{area}$  ( $p<0.001$ ;  
**1532** Table 4.4) was driven by a negative effect of increasing leaf  $C_i:C_a$  on  $N_{area}$  in  
**1533**  $C_3$  non-fixers and  $C_3$  N-fixers (Tukey:  $p<0.001$  in both cases), but not  $C_4$  non-  
**1534** fixers (Tukey:  $p=0.786$ ; Fig. 4.4a). A marginal interaction between soil nitrogen  
**1535** availability and plant functional group ( $p=0.057$ ; Table 4.4) indicated that the  
**1536** positive effect of increasing soil nitrogen ( $p=0.007$ ; Table 4.4) was only apparent  
**1537** in  $C_3$  N-fixers (Tukey:  $p<0.001$ ; Table 4.4; Fig. 4.4d), but not  $C_3$  non-fixers  
**1538** (Tukey:  $p=0.329$ ) or  $C_4$  non-fixers (Tukey:  $p=0.682$ ). Increasing soil moisture  
**1539** increased  $N_{area}$  ( $p=0.011$ , Table 4.4). A plant functional group effect ( $p<0.001$ ;  
**1540** Table 4.4) indicated that  $C_4$  non-fixers had lower  $N_{area}$  compared to  $C_3$  N-fixers  
**1541** and  $C_3$  non-fixers (Tukey:  $p<0.001$  in both cases), while  $C_3$  N-fixers had lower  
**1542**  $N_{area}$  compared to  $C_3$  non-fixers (Tukey:  $p=0.024$ ).

**1543** Leaf  $C_i:C_a$  had no effect on  $N_{mass}$  ( $p=0.455$ ; Table 4.4; Fig. 4.4b). Increas-  
**1544** ing soil nitrogen availability and soil moisture each had a positive effect on  $N_{mass}$   
**1545** ( $p<0.001$  in both cases; Table 4.4; Fig. 4.4h). A plant functional group effect  
**1546** ( $p<0.001$ ; Table 4.4) indicated that  $C_4$  non-fixers had lower  $N_{mass}$  compared to  
**1547**  $C_3$  N-fixers and  $C_3$  non-fixers (Tukey:  $p=0.001$  in both cases), while  $N_{mass}$  did  
**1548** not differ between  $C_3$  N-fixers and  $C_3$  non-fixers (Tukey:  $p=0.323$ ).

**1549** Variance in  $M_{area}$  was driven by a three-way interaction between soil nitro-  
**1550** gen availability, soil moisture, and plant functional group ( $p=0.018$ ; Table 4.4).  
**1551** This interaction indicated that increasing soil moisture increased the positive effect  
**1552** of increasing soil nitrogen availability on  $M_{area}$  in  $C_3$  N-fixers (Tukey:  $p=0.028$ )

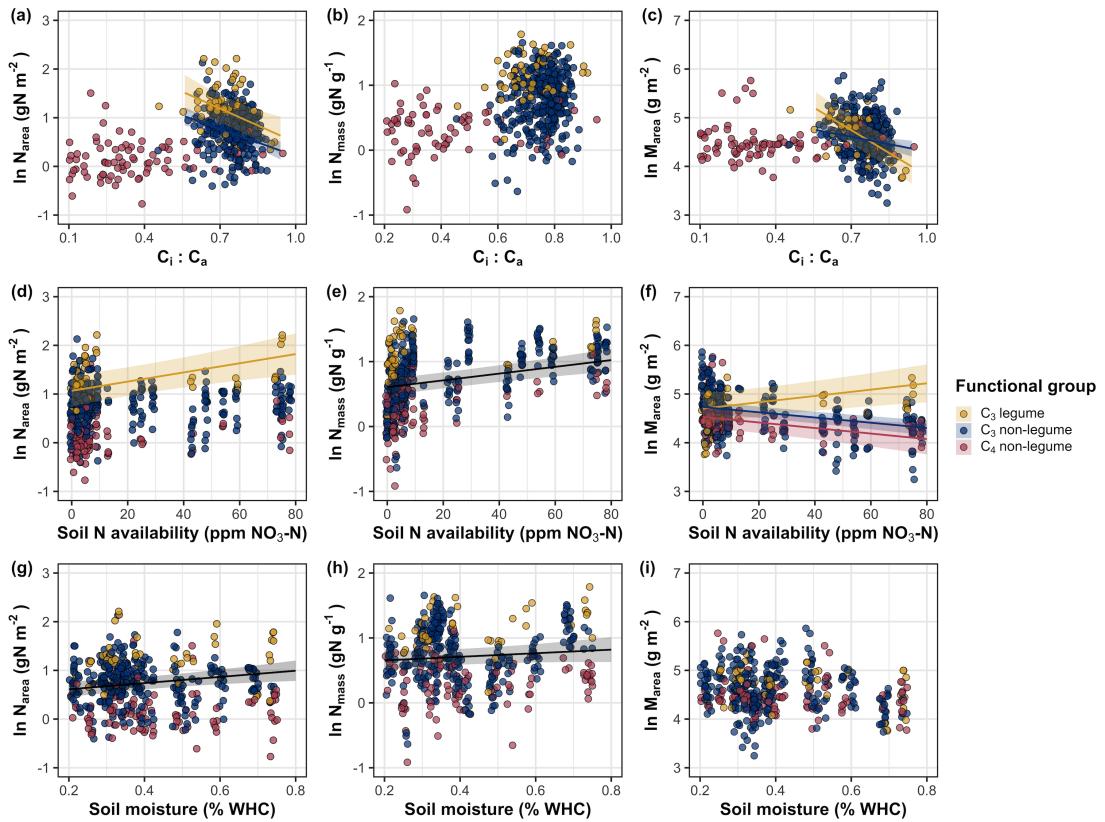

**1553** but did not modify the negative effect of increasing soil nitrogen availability on  
**1554**  $M_{\text{area}}$  in C<sub>4</sub> non-fixers (Tukey:  $p=0.806$ ) or C<sub>3</sub> non-fixers (Tukey:  $p=0.998$ ). There  
**1555** was otherwise no effect of soil moisture on  $M_{\text{area}}$  ( $p=0.436$ ; Table 4.4). An inter-  
**1556** action between leaf  $C_i:C_a$  and plant functional group ( $p<0.001$ ; Table 4.4; Fig.  
**1557** 4.4c) indicated that the negative effect of increasing leaf  $C_i:C_a$  on  $M_{\text{area}}$  ( $p<0.001$ ;  
**1558** Table 4.4) was driven by a negative effect of increasing leaf  $C_i:C_a$  on  $M_{\text{area}}$  in  
**1559** C<sub>3</sub> N-fixers (Tukey:  $p<0.001$ ) and C<sub>3</sub> non-fixers(Tukey:  $p=0.003$ ), but not C<sub>4</sub>  
**1560** non-fixers (Tukey:  $p=0.257$ ; Fig. 4.4c).

**Table 4.4.** Effects of soil moisture, soil nitrogen availability, plant functional group, and leaf  $C_i:C_a$  on leaf nitrogen content per unit leaf area ( $N_{\text{area}}$ ; gN m $^{-2}$ ), leaf nitrogen content per unit leaf biomass ( $N_{\text{mass}}$ ; gN g $^{-1}$ ), and leaf biomass per unit leaf area ( $M_{\text{area}}$ ; g m $^{-2}$ )

1561 \*Significance determined using Type II Wald  $\chi^2$  tests ( $\alpha=0.05$ ). P-values less than 0.05 are in bold and p-values  
 1562 where  $0.05 < p < 0.1$  are italicized. Coefficients are reported on the natural-log scale for all traits and are only included  
 1563 for continuous fixed effects. Key: df=degrees of freedom;  $\chi^2$ =Wald Type II chi-square test statistic

**Figure 4.4.** Effects of leaf  $C_i:C_a$  (a-c), soil nitrogen availability (d-f), and soil moisture (g-i) on leaf nitrogen content per unit leaf area (a, d, g), leaf nitrogen content per unit leaf biomass (b, e, h), and leaf mass per area (c, f, i). Yellow points and trendlines indicate  $C_3$  N-fixers, blue points and trendlines indicate  $C_3$  non-fixers, and red points and trendlines indicate  $C_4$  non-fixers. Points are jittered for visibility. Variably colored trendlines are only included if there is an interaction between plant functional group and the x-axis. Black solid trendlines denote bivariate slopes that are different from zero ( $p < 0.05$ ) where there is no apparent interaction between plant functional group and the x-axis.

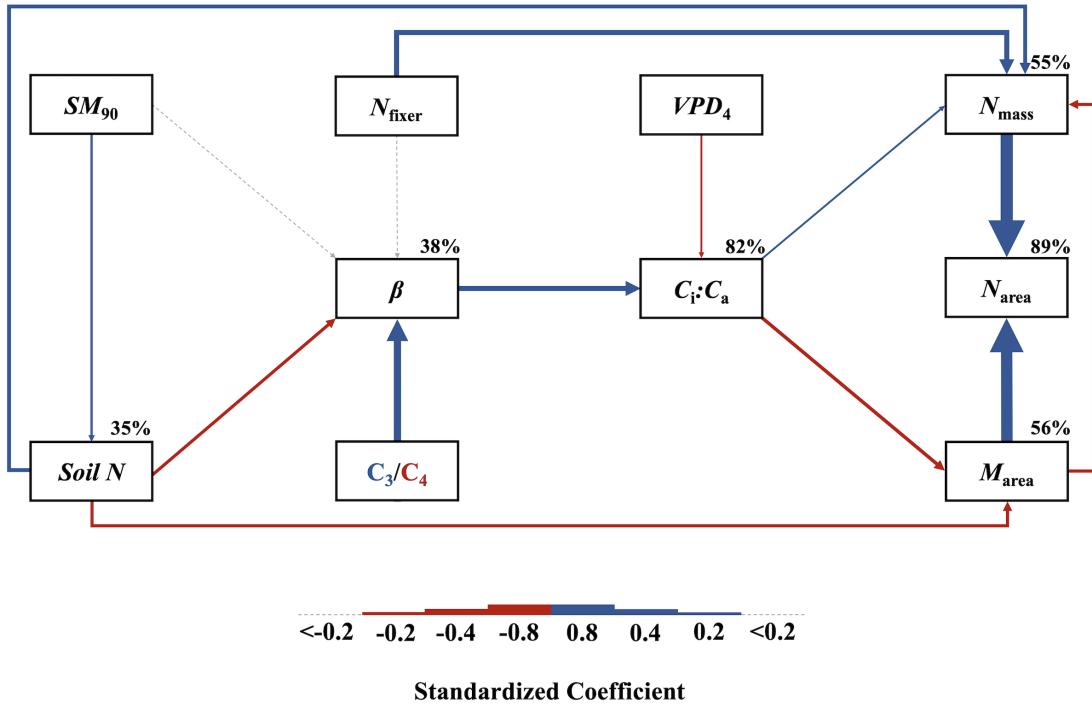

**1564** 4.3.4 *Structural equation model*

**1565** The piecewise structural equation model explained 89%, 55%, 56%, 82%, and  
**1566** 38% of variance in  $N_{\text{area}}$ ,  $N_{\text{mass}}$ ,  $M_{\text{area}}$ , leaf  $C_i:C_a$ , and  $\beta$ , respectively (Table  
**1567** 4.5; Fig. 4.5). Increasing  $N_{\text{mass}}$  and  $M_{\text{area}}$  were each positively related to  $N_{\text{area}}$   
**1568** ( $p<0.001$  in both cases; Table 4.5; Fig. 4.5).  $N_{\text{mass}}$  increased with increasing  
**1569** soil nitrogen availability ( $p<0.001$ ; Table 4.5) and leaf  $C_i:C_a$  ( $p=0.040$ ; Table  
**1570** 4.5), and was generally larger in N-fixing species ( $p<0.001$ ; Table 4.5), but was  
**1571** negatively related to increasing  $M_{\text{area}}$  ( $p<0.001$ ; Table 4.5).  $M_{\text{area}}$  decreased with  
**1572** increasing leaf  $C_i:C_a$  and soil nitrogen availability ( $p<0.001$  in both cases; Table  
**1573** 4.5). Leaf  $C_i:C_a$  declined with increasing vapor pressure deficit, but was positively  
**1574** related to  $\beta$  ( $p<0.001$  in both cases; Table 4.5).  $\beta$  decreased with increasing soil  
**1575** nitrogen availability and was higher in C<sub>3</sub> species ( $p<0.001$  in both cases; Table  
**1576** 4.5), but did not change with soil moisture ( $p=0.895$ ; Table 4.5) or with ability  
**1577** to acquire nitrogen via symbiotic nitrogen fixation ( $p=0.519$ ; Table 4.5). Finally,  
**1578** soil nitrogen availability was positively associated with increasing soil moisture  
**1579** ( $p=0.003$ ; Table 4.5; Fig. 4.5).

1580 \*Coefficients are standardized across the structural equation model. *P*-values less  
 1581 than 0.05 are noted in bold. Positive coefficients for photosynthetic pathway  
 1582 indicate generally larger values in C<sub>3</sub> species, while positive coefficients for N-  
 1583 fixing ability indicate generally larger values in N-fixing species. Key: df=degrees  
 1584 of freedom;  $\chi^2$ =Wald Type II chi-square test statistic;  $R^2_c$ =conditional R<sup>2</sup> value;  
 1585  $N_{\text{mass}}$ =leaf nitrogen content per unit leaf biomass (gN g<sup>-1</sup>);  $M_{\text{area}}$ =leaf mass per  
 1586 unit leaf biomass (g m<sup>-2</sup>);  $\beta$ =cost of acquiring nitrogen relative to water (unitless);  
 1587  $\text{VPD}_4$ =4-day mean vapor pressure deficit (kPa);  $\text{SM}_{90}$ =90-day mean soil moisture  
 1588 (mm)

**Figure 4.5.** Structural equation model results exploring drivers of  $N_{area}$ . Boxes indicate measured edaphic factors, climatic factors, and leaf traits. Solid arrows indicate bivariate relationships where  $p < 0.05$ , while dashed arrows indicate relationships where  $p > 0.05$ . Positive model coefficients are indicated through blue arrows, negative model coefficients are indicated through red arrows, and insignificant coefficients are indicated through gray dashed arrows. Arrow thickness scales with the standardized model coefficient of each bivariate relationship. A positive coefficient for photosynthetic pathway indicates larger values in  $C_3$  species, while a positive coefficient for  $N_{fixer}$  indicates larger values in N-fixing species. Standardized model coefficients and associated  $p$ -values are reported in Table 4.5, with conditional  $R^2$  values for each response variable reported on the top right of each box.

**1589** 4.4 Discussion

**1590** In this study, direct and indirect effects of edaphic and climatic characteristics on  
**1591**  $N_{\text{area}}$  and components of  $N_{\text{area}}$  ( $N_{\text{mass}}$  and  $M_{\text{area}}$ ) were quantified in 504 individuals  
**1592** spanning across a soil resource availability and climate gradient in Texas, USA.  
**1593** Consistent patterns emerged in support of those expected from photosynthetic  
**1594** least-cost theory, a result driven by a strong direct negative relationship between  
**1595** leaf  $C_i:C_a$  and  $N_{\text{area}}$  mediated through changes in  $M_{\text{area}}$ . In further support of  
**1596** patterns expected from theory, increasing soil nitrogen availability had a nega-  
**1597** tive effect on  $\beta$ , resulting in an indirect stimulation in  $N_{\text{area}}$  mediated through  
**1598** a positive relationship between  $\beta$  and  $C_i:C_a$ . Increasing vapor pressure deficit  
**1599** also indirectly increased  $N_{\text{area}}$  through a direct negative effect of increasing vapor  
**1600** pressure deficit on leaf  $C_i:C_a$ , following hypotheses and patterns expected from  
**1601** theory. Interestingly, a positive association between soil moisture and  $N_{\text{area}}$  was  
**1602** driven by covariance between soil moisture and soil nitrogen availability and was  
**1603** not associated with a direct effect of soil moisture on  $\beta$ . Overall, results provide  
**1604** strong and consistent support for patterns expected from photosynthetic least-cost  
**1605** theory, showing that both soil resource availability and climate drive variance in  
**1606**  $N_{\text{area}}$  through changes in leaf  $C_i:C_a$ .

**1607** 4.4.1 *Negative effects of leaf  $C_i:C_a$  on  $N_{\text{area}}$  are driven by reductions in  $M_{\text{area}}$ ,*  
**1608** *not  $N_{\text{mass}}$*

**1609** The negative response of  $N_{\text{area}}$  to increasing leaf  $C_i:C_a$  is consistent with pre-  
**1610** vious environmental gradient (Dong et al. 2017; Querejeta et al. 2022) and  
**1611** manipulation experiments (3.4c), showing strong support for the nitrogen-water

1612 use tradeoffs expected from photosynthetic least cost theory (Wright et al. 2003;  
1613 Prentice et al. 2014). Negative effects of increasing leaf  $C_i:C_a$  on  $N_{area}$  were driven  
1614 by negative effect of increasing leaf  $C_i:C_a$  on  $M_{area}$  coupled with a weak positive  
1615 effect of increasing leaf  $C_i:C_a$  on  $N_{mass}$ , suggesting that changes in  $N_{area}$  across  
1616 the environmental gradient were driven more strongly by changes in leaf morphol-  
1617 ogy than leaf chemistry. Interestingly, the negative relationship between  $M_{area}$   
1618 and  $N_{mass}$  suggested that stimulations in  $N_{mass}$  were often associated with larger,  
1619 thinner leaves (i.e., lower  $M_{area}$ ). These results are consistent with patterns re-  
1620 ported from previous studies indicating that variance in  $N_{area}$  is driven by changes  
1621 in  $M_{area}$  across environmental gradients, and that part of this response is due to  
1622 negative covariance between  $M_{area}$  and  $N_{mass}$  (Dong et al. 2017; Dong et al. 2020).  
1623 Negative covariance between  $M_{area}$  and  $N_{mass}$  could be a response associated with  
1624 tradeoffs between leaf longevity and leaf productivity (Wright et al. 2004; Dong  
1625 et al. 2017; Dong et al. 2022; Querejeta et al. 2022; Wang et al. 2023).

1626 The negative relationship between leaf  $C_i:C_a$  and  $M_{area}$  could be indicative  
1627 of tradeoffs between leaf longevity and leaf productivity. Tradeoffs between leaf  
1628 longevity and leaf productivity are commonly observed and are included in a  
1629 continuum of coordinated leaf traits that position individuals along a fast- or  
1630 slow-growing leaf economics spectrum (Wright et al. 2003; Onoda et al. 2004;  
1631 Reich 2014; Onoda et al. 2017; Wang et al. 2023). Negative relationships between  
1632 leaf  $C_i:C_a$  and  $M_{area}$  indicate that increased stomatal conductance and reduced  
1633 water use efficiency were associated with thinner, larger leaves (i.e., lower  $M_{area}$ ).  
1634 Combined with the negative covariance between  $M_{area}$  and  $N_{mass}$  mentioned above,  
1635 these responses may have allowed individuals to maximize light interception and

**1636** productivity by exploiting high light environments at the expense of increased  
**1637** water loss and decreased water-use efficiency. This strategy may be especially  
**1638** advantageous for fast-growing species in open canopy systems. In this study, C<sub>3</sub>  
**1639** N-fixers and C<sub>3</sub> non-fixers dominated the dataset (77% of total sampling effort),  
**1640** of which 23% (17% of total sampling effort) were classified as annual species with  
**1641** short growing seasons. We observed no effect of leaf  $C_i:C_a$  on  $N_{\text{area}}$  or  $M_{\text{area}}$  in C<sub>4</sub>  
**1642** non-fixers, which made up 23% of the sampling effort and were generally classified  
**1643** as warm season graminoid species with slower growth rates and longer growing  
**1644** seasons. These patterns indicate that stronger tradeoffs between nitrogen and  
**1645** water use may be more apparent in fast-growing species with high demand for  
**1646** building and maintaining productive leaf tissues.

**1647** 4.4.2 *Soil nitrogen availability increases  $N_{\text{area}}$  through changes in  $\beta$*   
**1648** The structural equation model indicated multiple pathways where increasing soil  
**1649** nitrogen availability increased  $N_{\text{area}}$ . First,  $N_{\text{area}}$  increased with increasing soil  
**1650** nitrogen availability due to larger positive direct effects of increasing soil nitrogen  
**1651** availability on  $N_{\text{mass}}$  than the corresponding negative direct effect of increasing  
**1652** soil nitrogen availability on  $M_{\text{area}}$ . These patterns corroborate those observed in  
**1653** the individual linear mixed effect models and previous work. Second, soil nitrogen  
**1654** availability increased  $N_{\text{area}}$  indirectly through reductions in  $\beta$ , which increased leaf  
**1655**  $C_i:C_a$  and stimulated  $N_{\text{area}}$  through a stronger negative effect of increasing leaf  
**1656**  $C_i:C_a$  on  $M_{\text{area}}$  than corresponding positive effect of increasing leaf  $C_i:C_a$  on  $N_{\text{mass}}$ .  
**1657** Reductions in  $\beta$  with increasing soil nitrogen availability were likely driven by re-  
**1658** ductions in the cost of acquiring and using nitrogen, following patterns observed

1659 in previous experiments (Bae et al. 2015; Eastman et al. 2021; Perkowski et al.  
1660 2021; Lu et al. 2022). These pathways indicate that soil nitrogen availability can  
1661 have direct positive effects on  $N_{\text{area}}$  by increasing leaf nitrogen concentration, fol-  
1662 lowing previous work (Firn et al. 2019; Liang et al. 2020), or can alternatively have  
1663 indirect positive effects on  $N_{\text{area}}$  through changes in leaf morphology associated  
1664 with a reduction in the cost of acquiring nitrogen, following patterns expected  
1665 from photosynthetic least-cost theory. Results reported here indicate that pho-  
1666 tosynthetic least-cost frameworks are capable of detecting predictable variance in  
1667  $N_{\text{area}}$  and tradeoffs between nitrogen and water use across soil nitrogen availability  
1668 gradients.

1669 4.4.3 *Soil moisture increases  $N_{\text{area}}$  by facilitating increases in soil nitrogen  
1670 availability*

1671 Increasing soil moisture had a positive effect on  $N_{\text{area}}$ , though this response was  
1672 associated with a null effect of soil moisture on  $\beta$ . These results contrast patterns  
1673 expected from theory, where increasing soil moisture is expected to indirectly  
1674 decrease  $N_{\text{area}}$  through an increase in  $\beta$  due to a reduction in costs associated  
1675 with water acquisition and use (Wright et al. 2003; Prentice et al. 2014; Lavergne  
1676 et al. 2020). Interestingly, structural equation model results revealed a strong  
1677 positive association between soil moisture and soil nitrogen availability, indicating  
1678 an indirect positive effect of increasing soil moisture on  $N_{\text{area}}$  mediated by the  
1679 negative effect of increasing soil nitrogen availability on  $\beta$ . In Texan grasslands,  
1680 productivity and nutrient uptake are often co-limited by precipitation and nutrient  
1681 availability (Yahdjian et al. 2011; Wang et al. 2017). Thus, increases in soil  
1682 moisture may have facilitated more favorable and productive environments for  
1683 soil microbial communities (Reichman et al. 1966; Stark and Firestone 1995;

1684 Paul et al. 2003), or alternatively greater nitrogen mobility in soil solution. As  
1685 discussed above, the positive indirect response of  $N_{\text{area}}$  to increasing soil nitrogen  
1686 availability as mediated through reductions in  $\beta$  follow patterns expected from  
1687 theory.

1688 4.4.4 *Indirect effects of climate on  $N_{\text{area}}$  are mediated through changes in leaf*  
1689  $C_i:C_a$  *and  $\beta$*

1690 In support of hypotheses and patterns expected from theory, increasing vapor  
1691 pressure deficit indirectly increased  $N_{\text{area}}$ , mediated through the negative effect  
1692 of increasing vapor pressure deficit on leaf  $C_i:C_a$ . These responses are consistent  
1693 with previous work noting strong reductions in stomatal conductance with increas-  
1694 ing vapor pressure deficit (Oren et al. 1999; Novick et al. 2016; Sulman et al.  
1695 2016; Grossiord et al. 2020; López et al. 2021), a response that allows plants  
1696 to minimize water loss as a result of high atmospheric water demand. Results  
1697 also support findings from previous experiments across environmental gradients,  
1698 where increasing vapor pressure deficit generally increases  $N_{\text{area}}$  at lower stomatal  
1699 conductance across environmental gradients (Dong et al. 2017; Dong et al. 2022;  
1700 Paillassa et al. 2020; Westerband et al. 2023). The increase in  $N_{\text{area}}$  with increas-  
1701 ing vapor pressure deficit could allow plants to maximize photosynthetic capacity  
1702 under reduced stomatal conductance (Dong et al. 2022), though this pattern con-  
1703 trasts previous work suggesting that long-term increases in vapor pressure deficit  
1704 are associated with increased plant mortality, reduced net primary productivity,  
1705 and perhaps reductions in net photosynthesis rates over time due to prolonged  
1706 stomatal closure (Eamus et al. 2013; Yuan et al. 2019; Grossiord et al. 2020).  
1707 Importantly, such negative effects of increasing vapor pressure deficit often occur  
1708 along much broader timescales compared to the timescale used here. Responses

1709 observed here suggest that variance in  $N_{\text{area}}$  across environmental gradients is  
1710 a deterministic acclimation response to changing aboveground climate, allowing  
1711 plants to satisfy demand to build and maintain photosynthetic enzymes and op-  
1712 timize photosynthetic processes by maximizing resource use efficiency (Paillassa  
1713 et al. 2020; Peng et al. 2021; Dong et al. 2022; Westerband et al. 2023).

1714 4.4.5 *Species identity traits modify effects of the environment on  $\beta$ , leaf  $C_i:C_a$ ,*  
1715 *and  $N_{\text{area}}$*

1716 N-fixing species had greater  $N_{\text{area}}$  values on average compared to non-fixing species,  
1717 a pattern driven by a stronger stimulation in  $N_{\text{mass}}$  in N-fixing species coupled with  
1718 no change in  $M_{\text{area}}$  between species with different N-fixation ability. There was  
1719 no evidence to suggest that N-fixing species had different  $\beta$  or leaf  $C_i:C_a$  values  
1720 compared to non-fixing species across the environmental gradient. These results  
1721 follow patterns from previous environmental gradient experiments that investi-  
1722 gate variance in leaf nitrogen allocation in N-fixing species (Adams et al. 2016;  
1723 Dong et al. 2017; Dong et al. 2020), and that increases in  $N_{\text{mass}}$  and  $N_{\text{area}}$  in  
1724 N-fixing species are not necessarily correlated to increases in water use efficiency  
1725 or reductions in leaf  $C_i:C_a$  (Adams et al. 2016). While results are consistent with  
1726 results from previous environmental gradient experiments, they do not support  
1727 hypotheses presented here or patterns expected from theory, which predicts that  
1728 stimulations in  $N_{\text{area}}$  by N-fixing species should be driven by a reduction in  $\beta$   
1729 relative to non-fixing species, and that this response should decrease stomatal  
1730 conductance and leaf  $C_i:C_a$ .

1731 C<sub>4</sub> species had reduced  $\beta$ , leaf  $C_i:C_a$ , and  $N_{\text{area}}$  than C<sub>3</sub> species. Reduced  
1732  $\beta$  and leaf  $C_i:C_a$  values in C<sub>4</sub> species follow hypotheses listed above, a pattern

1733 that could be the result of either reduced costs of nitrogen acquisition and use,  
1734 increased costs of water acquisition and use, or both (Wright et al. 2003; Prentice  
1735 et al. 2014). Results also indicate that  $\beta$  in C<sub>4</sub> non-fixers was unresponsive to  
1736 changes in soil nitrogen availability despite an apparent negative effect of increas-  
1737 ing soil nitrogen availability on  $\beta$  in C<sub>3</sub> N-fixers and C<sub>3</sub> non-fixers. Combined  
1738 with a general null response of  $\beta$  to soil moisture regardless of plant functional  
1739 group, these patterns imply that reduced  $\beta$  values in C<sub>4</sub> species may be the re-  
1740 sult of lower costs of nitrogen acquisition and use relative to C<sub>3</sub> species. While  
1741 lower  $\beta$  values in C<sub>4</sub> species provides a possible explanation for why C<sub>4</sub> species  
1742 often have lower leaf C<sub>i</sub>:C<sub>a</sub> and greater water use efficiency, theory predicts that  
1743 this response should cause C<sub>4</sub> species to have greater N<sub>area</sub> values compared to  
1744 C<sub>3</sub> species, though C<sub>4</sub> species commonly exhibit lower N<sub>area</sub> and higher nitrogen  
1745 use efficiency than C<sub>3</sub> species (Schmitt and Edwards 1981; Sage and Pearcy 1987;  
1746 Ghannoum et al. 2011). We speculate that lowered costs of nitrogen acquisition  
1747 and use in C<sub>4</sub> species could be driven by more efficient Rubisco carboxylation effi-  
1748 ciency in C<sub>4</sub> species associated with CO<sub>2</sub> concentrating mechanisms that eliminate  
1749 photorespiration (Ghannoum et al. 2011), which could reduce or eliminate the  
1750 need to sacrifice inefficient nitrogen use for efficient water use to achieve optimal  
1751 photosynthesis rates.

1752 4.4.6 *Next steps for optimality model development*

1753 Optimality models for both C<sub>3</sub> and C<sub>4</sub> species have been developed using principles  
1754 from photosynthetic least-cost theory (Prentice et al. 2014; Wang et al. 2017;  
1755 Smith et al. 2019; Stocker et al. 2020; Scott and Smith 2022). In both C<sub>3</sub> and C<sub>4</sub>  
1756 model variants,  $\beta$  values are held constant using global datasets of leaf δ<sup>13</sup>C (Wang

1757 et al. 2017; Cornwell et al. 2018). Specifically, the C<sub>3</sub> optimality model initially  
1758 assumed a constant  $\beta$  value of 240 (Wang et al. 2017), later corrected to 146  
1759 (Stocker et al. 2020), while the C<sub>4</sub> optimality model assumes a constant  $\beta$  value of  
1760 166 (Scott and Smith 2022). These results, which build on findings from Paillassa  
1761 et al. (2020) and Lavergne et al. (2020), demonstrate high variability in calculated  
1762  $\beta$  values across the environmental gradient. Specifically,  $\beta$  values in C<sub>3</sub> species  
1763 ranged from 1.7 to 188.0 (mean: 30.2; median: 23.1; standard deviation: 25.4),  
1764 while ranged from 0.1 to 110.6 in C<sub>4</sub> species (mean: 7.2; median: 0.7; standard  
1765 deviation: 18.6). Mean  $\beta$  values in both C<sub>3</sub> and C<sub>4</sub> species were consistently lower  
1766 than values currently implemented in optimality models, though this was likely  
1767 the result of increased water limitation across sites relative to global averages.  
1768 Regardless, the high degree of  $\beta$  variability across this environmental gradient,  
1769 together with findings from Lavergne et al. (2020) and Paillassa et al. (2020),  
1770 suggests that the use of constant  $\beta$  values may contribute to erroneous errors when  
1771 conducting optimality model simulations. Results from this experiment build  
1772 on suggestions from Wang et al. (2017), suggesting that future photosynthetic  
1773 least-cost optimality model developments should consider adopting frameworks  
1774 for dynamically calculating  $\beta$ .

1775 4.4.7 *Conclusions*

1776 To summarize, variability in  $N_{\text{area}}$  across an environmental gradient in Texan  
1777 grasslands was driven by indirect effects of climate and soil resource availability  
1778 mediated by changes in  $\beta$  and leaf  $C_i:C_a$ . Results from this experiment provide  
1779 strong and consistent support for patterns expected from photosynthetic least-

**1780** cost theory, demonstrating that negative relationships between  $C_i:C_a$  and  $N_{\text{area}}$   
**1781** unify expected effects of climatic and edaphic characteristics on  $N_{\text{area}}$  across en-  
**1782** vironmental gradients. Results reported here also demonstrate a need to consider  
**1783** the dynamic nature of the relative cost of nitrogen versus water uptake ( $\beta$ ) across  
**1784** environmental gradients in optimality models that leverage principles of photo-  
**1785** synthetic least-cost theory.

**1786**

## Chapter 5

**1787** Optimal resource investment to photosynthetic capacity maximizes  
**1788** nutrient allocation to whole plant growth under elevated CO<sub>2</sub>

**1789** 5.1 Introduction

**1790** Terrestrial ecosystems are regulated by complex carbon and nitrogen cycles. As  
**1791** a result, terrestrial biosphere models, which are beginning to include coupled  
**1792** carbon and nitrogen cycles (Shi et al. 2016; Davies-Barnard et al. 2020; Braghieri  
**1793** et al. 2022), must accurately represent these cycles under different environmental  
**1794** scenarios to reliably simulate carbon and nitrogen atmosphere-biosphere fluxes  
**1795** (Hungate et al. 2003; Prentice et al. 2015). While the inclusion of coupled carbon  
**1796** and nitrogen cycles tends to reduce model uncertainty (Arora et al. 2020), large  
**1797** uncertainty in role of soil nitrogen availability and nitrogen acquisition strategy  
**1798** on leaf and whole plant acclimation responses to CO<sub>2</sub> remains (Smith and Dukes  
**1799** 2013; Terrer et al. 2018; Smith and Keenan 2020). This source of uncertainty  
**1800** likely contributes to the widespread divergence in future carbon and nitrogen flux  
**1801** simulations across terrestrial biosphere models (Friedlingstein et al. 2014; Zaehle  
**1802** et al. 2014; Meyerholt et al. 2020).

**1803** Plants grown under elevated CO<sub>2</sub> generally have less leaf nitrogen content  
**1804** than those grown under ambient CO<sub>2</sub>, a response that often corresponds with  
**1805** reductions in photosynthetic capacity and stomatal conductance at the leaf-level  
**1806** and biomass stimulation over time at the whole plant level (Curtis 1996; Drake  
**1807** et al. 1997; Ainsworth et al. 2002; Makino 2003; Morgan et al. 2004; Ainsworth  
**1808** and Long 2005; Ainsworth and Rogers 2007; Smith and Dukes 2013; Poorter et al.  
**1809** 2022). As net primary productivity is generally limited by nitrogen availability

1810 (Vitousek and Howarth 1991; LeBauer and Treseder 2008; Fay et al. 2015), and  
1811 soil nitrogen availability is often positively correlated with leaf nitrogen content  
1812 and photosynthetic capacity (Field and Mooney 1986; Evans and Seemann 1989;  
1813 Evans 1989; Walker et al. 2014; Firn et al. 2019; Liang et al. 2020), some  
1814 have hypothesized that leaf and whole plant acclimation responses to CO<sub>2</sub> are  
1815 constrained by soil nitrogen availability.

1816 The progressive nitrogen limitation hypothesis predicts that elevated CO<sub>2</sub>  
1817 will increase plant nitrogen demand, which will increase plant nitrogen uptake  
1818 and progressively deplete soil nitrogen if soil nitrogen supply does not exceed  
1819 plant nitrogen demand (Luo et al. 2004). The hypothesis predicts that this  
1820 response should result in strong acute stimulations in whole plant growth and  
1821 primary productivity that diminish over time as nitrogen becomes more limiting.  
1822 Assuming a positive relationship between soil nitrogen availability, leaf nitrogen  
1823 content, and photosynthetic capacity, this hypothesis also implies that progressive  
1824 reductions in soil nitrogen availability should be the mechanism that drives the  
1825 reduction in leaf nitrogen content and photosynthetic capacity under elevated  
1826 CO<sub>2</sub>. The progressive nitrogen limitation hypothesis has received some support  
1827 from free air CO<sub>2</sub> enrichment experiments (Reich et al. 2006; Norby et al. 2010),  
1828 although is not consistently observed across experiments (Finzi et al. 2006; Moore  
1829 et al. 2006; Liang et al. 2016).

1830 While possible that progressive nitrogen limitation may determine leaf and  
1831 whole plant acclimation responses to CO<sub>2</sub>, growing evidence indicates that leaf ni-  
1832 trogen content and photosynthetic capacity are more strongly determined through  
1833 aboveground growing conditions than by soil resource availability (Dong et al.

1834 2017; Dong et al. 2020; Dong et al. 2022; Smith et al. 2019; Smith and Keenan  
1835 2020; Paillassa et al. 2020; Peng et al. 2021; Querejeta et al. 2022; Wester-  
1836 band et al. 2023), and satellite-derived chlorophyll fluorescence data indicate that  
1837 increasing atmospheric CO<sub>2</sub> may decrease leaf and canopy demand for nitrogen  
1838 (Dong et al. 2022). Together, results from these studies suggest that the re-  
1839 duction in leaf nitrogen content and photosynthetic capacity due to increasing  
1840 CO<sub>2</sub> may not be as tightly linked to progressive nitrogen limitation as previously  
1841 hypothesized.

1842 A unification of optimal coordination and least-cost theories predicts that  
1843 leaves acclimate to elevated CO<sub>2</sub> by reducing nitrogen allocation to Ribulose-  
1844 1,5-bisphosphate (RuBP) carboxylase/oxygenase (Rubisco) to optimize resource  
1845 use efficiencies at the leaf level, which allows for greater resource allocation to  
1846 whole plant growth (Drake et al. 1997; Wright et al. 2003; Prentice et al. 2014;  
1847 Smith et al. 2019). The theory predicts that the reduction in nitrogen allocation  
1848 to Rubisco results in a stronger reduction in the maximum rate of Rubisco car-  
1849 boxylation ( $V_{cmax}$ ) than the maximum rate of RuBP regeneration ( $J_{max}$ ), which  
1850 maximizes photosynthetic efficiency by allowing net photosynthesis rates to be  
1851 equally co-limited by Rubisco carboxylation and RuBP regeneration (Chen et al.  
1852 1993; Maire et al. 2012). This acclimation response allows plants to make more  
1853 efficient use of available light while avoiding overinvestment in Rubisco, which  
1854 has high nitrogen and energetic costs of building and maintaining (Evans 1989;  
1855 Evans and Clarke 2019). Instead, additional acquired resources not needed to  
1856 optimize leaf photosynthesis are allocated to the maintenance of structures that  
1857 support whole plant growth (e.g., total leaf area, whole plant biomass, etc.) or

1858 to allocation processes not related to leaf photosynthesis or growth, such as plant  
1859 defense mechanisms. Regardless, optimized resource allocation at the leaf level  
1860 should allow for greater resource allocation to whole plant growth. The theory  
1861 indicates that leaf acclimation responses to CO<sub>2</sub> should be independent of changes  
1862 in soil nitrogen availability. While this leaf acclimation response maximizes nitro-  
1863 gen allocation to structures that support whole plant growth, the theory suggests  
1864 that the positive effect of elevated CO<sub>2</sub> on whole plant growth may be further  
1865 stimulated by soil nitrogen availability through reductions in the cost of acquiring  
1866 nitrogen (Bae et al. 2015; Perkowski et al. 2021; Lu et al. 2022).

1867 Plants acquire nitrogen by allocating photosynthetically derived carbon be-  
1868 lowground in exchange for nitrogen through different nitrogen acquisition strate-  
1869 gies. These nitrogen acquisition strategies can include direct uptake pathways  
1870 such as mass flow or diffusion (Barber 1962), symbioses with mycorrhizal fungi or  
1871 symbiotic nitrogen-fixing bacteria (Vance and Heichel 1991; Marschner and Dell  
1872 1994; Smith and Read 2008; Udvardi and Poole 2013), or through the release  
1873 of root exudates that prime free-living soil microbial communities (Phillips et al.  
1874 2011; Wen et al. 2022). Plants cannot acquire nitrogen without first allocating  
1875 carbon belowground, which implies an inherent carbon cost to the plant for acquir-  
1876 ing nitrogen regardless of nitrogen acquisition strategy. Carbon costs to acquire  
1877 nitrogen often vary in species with different nitrogen acquisition strategies and  
1878 are dependent on external environmental factors such as atmospheric CO<sub>2</sub>, light  
1879 availability, and soil nitrogen availability (Brzostek et al. 2014; Terrer et al. 2016;  
1880 Terrer et al. 2018; Allen et al. 2020; Perkowski et al. 2021; Lu et al. 2022). These  
1881 patterns suggest that acquisition strategy may at least partially determine the net

1882 effect of soil nitrogen availability on leaf and whole plant acclimation responses to  
1883 elevated CO<sub>2</sub>.

1884 A recent meta-analysis using data across 20 grassland and forest CO<sub>2</sub> en-  
1885 richment experiments suggested that species which acquire nitrogen from sym-  
1886 biotic nitrogen-fixing bacteria had reduced costs of nitrogen acquisition under  
1887 elevated CO<sub>2</sub> (Terrer et al. 2018). Though these analyses included data from two  
1888 experimental sites, findings from this meta-analysis indicated that reduced costs  
1889 of nitrogen acquisition in species that form associations with symbiotic nitrogen-  
1890 fixing bacteria under elevated CO<sub>2</sub> may drive stronger increases in whole plant  
1891 growth and reductions in  $V_{cmax}$  than species that associate with arbuscular my-  
1892 corrhizal fungi (Smith and Keenan 2020), which generally have greater costs of  
1893 nitrogen acquisition under elevated CO<sub>2</sub> (Terrer et al. 2018). However, plant in-  
1894 vestments in symbiotic nitrogen fixation generally decline with increasing nitrogen  
1895 availability (Dovrat et al. 2018; Perkowski et al. 2021), a response that has been  
1896 previously inferred to driven by a shift to direct uptake pathways as costs of direct  
1897 uptake decrease (Rastetter et al. 2001; Perkowski et al. 2021). Thus, effects of  
1898 symbiotic nitrogen fixation on plant acclimation responses to CO<sub>2</sub> should decline  
1899 with increasing soil nitrogen availability, although manipulative experiments that  
1900 directly test these patterns are rare.

1901 Here, I conducted a 7-week growth chamber experiment using *Glycine max*  
1902 L. (Merr.) to examine the effects of soil nitrogen fertilization and inoculation with  
1903 symbiotic nitrogen-fixing bacteria on leaf and whole plant acclimation responses to  
1904 elevated CO<sub>2</sub>. Following patterns expected from theory, I hypothesized that indi-  
1905 vidual leaves should acclimate to elevated CO<sub>2</sub> by more strongly decreasing  $V_{cmax}$

1906 relative to  $J_{\max}$ , allowing leaf photosynthesis to approach optimal coordination.  
1907 I expected this response to correspond with a stronger reduction in leaf nitrogen  
1908 content than  $V_{c\max}$  and  $J_{\max}$ , which would increase the fraction of leaf nitrogen  
1909 content allocated to photosynthesis. At the whole-plant level, I hypothesized that  
1910 plants would acclimate to elevated CO<sub>2</sub> by increasing whole plant growth and  
1911 productivity, a response that would be driven by an increase in total leaf area and  
1912 aboveground biomass. I predicted that leaf acclimation responses to elevated CO<sub>2</sub>  
1913 would be independent of soil nitrogen fertilization and inoculation with symbiotic  
1914 nitrogen-fixing bacteria. However, I expected that increasing fertilization would  
1915 increase the positive effect of elevated CO<sub>2</sub> on total leaf area and aboveground  
1916 biomass due to a stronger reduction in the cost of acquiring nitrogen under ele-  
1917 vated CO<sub>2</sub> with increasing fertilization. Finally, I expected stronger increases in  
1918 whole plant growth under elevated CO<sub>2</sub> in inoculated pots, but expected that this  
1919 effect would only be apparent under low fertilization due to a reduction in root  
1920 nodulation with increasing fertilization.

1921 5.2 Methods

1922 5.2.1 *Seed treatments and experimental design*

1923 *Glycine max* L. (Merr) seeds were planted in 144 6-liter surface sterilized pots (NS-  
1924 600, Nursery Supplies, Orange, CA, USA) containing a steam-sterilized 70:30 v:v  
1925 mix of *Sphagnum* peat moss (Premier Horticulture, Quakertown, PA, USA) to  
1926 sand (Pavestone, subsidiary of Quikrete Companies, Atlanta, GA, USA). Before  
1927 planting, all *G. max* seeds were surface sterilized in 2% sodium hypochlorite for 3  
1928 minutes, followed by three separate 3-minute washes with ultrapure water (MilliQ

1929 7000; MilliporeSigma, Burlington, MA USA). A subset of surface sterilized seeds  
1930 were inoculated with *Bradyrhizobium japonicum* (Verdesian N-Dure<sup>TM</sup> Soybean,  
1931 Cary, NC, USA) in a slurry following manufacturer recommendations (3.12 g  
1932 inoculant and 241 g deionized water per 1 kg seed).

1933 Seventy-two pots were randomly planted with surface-sterilized seeds inoc-  
1934 ulated with *B. japonicum*, while the remaining 72 pots were planted with surface-  
1935 sterilized uninoculated seeds. Thirty-six pots within each inoculation treatment  
1936 were randomly placed in one of two atmospheric CO<sub>2</sub> treatments (ambient and  
1937 1000  $\mu\text{mol mol}^{-1}$  CO<sub>2</sub>). Pots within each unique inoculation-by-CO<sub>2</sub> treatment  
1938 combination randomly received one of nine soil nitrogen fertilization treatments  
1939 equivalent to 0, 35, 70, 105, 140, 210, 280, 350, or 630 ppm N. Nitrogen fertil-  
1940 ization treatments were created using a modified Hoagland solution (Hoagland  
1941 and Arnon 1950) designed to keep concentrations of other macronutrients and  
1942 micronutrients equivalent across treatments (Table D1). Pots received the same  
1943 fertilization treatment throughout the entire duration experiment, which were ap-  
1944 plied twice per week in 150 mL doses as topical agents to the soil surface. This  
1945 experimental design yielded a fully factorial experiment with four replicates per  
1946 unique fertilization-by-inoculation-by-CO<sub>2</sub> combination.

#### 1947 5.2.2 *Growth chamber conditions*

1948 Upon experiment initiation, pots were randomly placed in one of six Percival  
1949 LED-41L2 growth chambers (Percival Scientific Inc., Perry, IA, USA) over two  
1950 experimental iterations due to chamber space limitation. Two iterations were  
1951 conducted such that one iteration included all elevated CO<sub>2</sub> pots and the second

1952 iteration included all ambient CO<sub>2</sub> pots. Mean ( $\pm$  SD) CO<sub>2</sub> concentrations across  
1953 chambers throughout the experiment were  $439 \pm 5 \mu\text{mol mol}^{-1}$  CO<sub>2</sub> for the ambient  
1954 CO<sub>2</sub> treatment and  $989 \pm 4 \mu\text{mol mol}^{-1}$  CO<sub>2</sub> for the elevated CO<sub>2</sub> treatment.

1955 Daytime growing conditions were simulated using a 16-hour photoperiod,  
1956 with incoming light radiation set to chamber maximum (mean  $\pm$  SD:  $1240 \pm 32$   
1957  $\mu\text{mol m}^{-2} \text{s}^{-1}$  across chambers), air temperature set to 25°C, and relative humid-  
1958 ity set to 50%. The remaining 8 hours simulated nighttime growing conditions,  
1959 with incoming light radiation set to 0  $\mu\text{mol m}^{-2} \text{s}^{-1}$ , chamber temperature set  
1960 to 17°C, and relative humidity set to 50%. Transitions between daytime and  
1961 nighttime growing conditions were simulated by ramping incoming light radiation  
1962 in 45-minute increments and temperature in 90-minute increments over a 3-hour  
1963 period (Table D2).

1964 Including the two, 3-hour ramping periods, pots grew under average ( $\pm$  SD)  
1965 daytime light intensity of  $1049 \pm 27 \mu\text{mol m}^{-2} \text{s}^{-1}$ . In the elevated CO<sub>2</sub> iteration,  
1966 pots grew under  $24.0 \pm 0.2^\circ\text{C}$  during the day,  $16.4 \pm 0.8^\circ\text{C}$  during the night, and  
1967 51.6  $\pm 0.4\%$  relative humidity. In the ambient CO<sub>2</sub> iteration, pots grew under  
1968  $23.9 \pm 0.2^\circ\text{C}$  during the day,  $16.0 \pm 1.4^\circ\text{C}$  during the night, and 50.3  $\pm 0.2\%$  relative  
1969 humidity. I accounted for any climatic differences across the six chambers by  
1970 shuffling the same group of pots daily throughout the growth chambers. This  
1971 process was done by iteratively moving the group of pots on the top rack of a  
1972 chamber to the bottom rack of the same chamber, while simultaneously moving  
1973 the group of pots on the bottom rack of a chamber to the top rack of the adjacent  
1974 chamber. I moved pots within and across chambers every day throughout the  
1975 course of each experiment iteration.

**1976** 5.2.3 *Leaf gas exchange measurements*

**1977** Gas exchange measurements were collected for all individuals on the seventh week  
**1978** of development. All gas exchange measurements were collected on the center leaf  
**1979** of the most recent fully expanded trifoliate leaf set. Specifically, I measured net  
**1980** photosynthesis ( $A_{\text{net}}$ ;  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ), stomatal conductance ( $g_{\text{sw}}$ ;  $\text{mol m}^{-2} \text{s}^{-1}$ ),  
**1981** and intercellular  $\text{CO}_2$  ( $C_i$ ;  $\mu\text{mol mol}^{-1}$ ) concentrations across a range of atmo-  
**1982** spheric  $\text{CO}_2$  concentrations (i.e., an  $A_{\text{net}}/C_i$  curve) using the Dynamic Assimila-  
**1983** tion Technique™. The Dynamic Assimilation Technique™ has been shown to  
**1984** correspond well with traditional steady-state  $\text{CO}_2$  response curves in *G. max*  
**1985** (Saathoff and Welles 2021).  $A_{\text{net}}/C_i$  curves were generated along a reference  $\text{CO}_2$   
**1986** ramp down from  $420 \mu\text{mol mol}^{-1} \text{CO}_2$  to  $20 \mu\text{mol mol}^{-1} \text{CO}_2$ , followed by a ramp  
**1987** up from  $420 \mu\text{mol mol}^{-1} \text{CO}_2$  to  $1620 \mu\text{mol mol}^{-1} \text{CO}_2$  after a 90-second wait  
**1988** period at  $420 \mu\text{mol mol}^{-1} \text{CO}_2$ . The ramp rate for each curve was set to  $200$   
**1989**  $\mu\text{mol mol}^{-1} \text{min}^{-1}$ , logging every five seconds, which generated 96 data points per  
**1990** response curve. All  $A_{\text{net}}/C_i$  curves were generated after  $A_{\text{net}}$  and  $g_{\text{sw}}$  stabilized  
**1991** in a LI-6800 cuvette set to a  $500 \text{ mol s}^{-1}$ , 10,000 rpm mixing fan speed,  $1.5 \text{ kPa}$   
**1992** vapor pressure deficit,  $25^\circ\text{C}$  leaf temperature,  $2000 \mu\text{mol m}^{-2} \text{s}^{-1}$  incoming light  
**1993** radiation, and initial reference  $\text{CO}_2$  set to  $420 \mu\text{mol mol}^{-1}$ .

**1994** With the same focal leaf used to generate  $A_{\text{net}}/C_i$  curves, I measured dark  
**1995** respiration ( $R_{\text{d25}}$ ;  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ) following at least a 30-minute period of darkness.  
**1996** Measurements were collected on a 5-second log interval for 60 seconds after stabi-  
**1997** lizing in a LI-6800 cuvette set to a  $500 \text{ mol s}^{-1}$ , 10,000 rpm mixing fan speed,  $1.5$   
**1998**  $\text{kPa}$  vapor pressure deficit,  $25^\circ\text{C}$  leaf temperature, and  $420 \mu\text{mol mol}^{-1}$  reference  
**1999**  $\text{CO}_2$  concentration (for both  $\text{CO}_2$  concentrations), with incoming light radiation

**2000** set to 0  $\mu\text{mol m}^{-2} \text{s}^{-1}$ . A single dark respiration value was determined for each  
**2001** focal leaf by calculating the mean dark respiration value (i.e. the absolute value  
**2002** of  $A_{\text{net}}$  during the logging period) across the logging interval.

**2003** 5.2.4 *Leaf trait measurements*

**2004** The focal leaf used to generate  $A_{\text{net}}/C_i$  curves and dark respiration was harvested  
**2005** immediately following gas exchange measurements. Images of each focal leaf were  
**2006** curated using a flat-bed scanner to determine wet leaf area using the ‘LeafArea’ R  
**2007** package (Katabuchi 2015), which automates leaf area calculations using ImageJ  
**2008** software (Schneider et al. 2012). Each leaf was dried at 65°C for at least 48  
**2009** hours, and subsequently weighed and ground until homogenized. Leaf mass per  
**2010** area ( $M_{\text{area}}$ ; g  $\text{m}^{-2}$ ) was calculated as the ratio of dry leaf biomass to fresh leaf  
**2011** area. Using subsamples of ground and homogenized leaf tissue, I measured leaf  
**2012** nitrogen content ( $N_{\text{mass}}$ ; gN  $\text{g}^{-1}$ ) through elemental combustion analysis (Costech-  
**2013** 4010, Costech, Inc., Valencia, CA, USA). Leaf nitrogen content per unit leaf area  
**2014** ( $N_{\text{area}}$ ; gN  $\text{m}^{-2}$ ) was calculated by multiplying  $N_{\text{mass}}$  and  $M_{\text{area}}$ . Subsamples of  
**2015** ground and homogenized leaf tissue were also sent to the UC-Davis Stable Isotope  
**2016** Facility to quantify leaf  $\delta^{15}\text{N}$ , later used to estimate the fraction of leaf nitrogen  
**2017** derived from the atmosphere.

**2018** I extracted chlorophyll content from a second leaf in the same trifoliolate  
**2019** leaf set as the focal leaf used to generate  $A_{\text{net}}/C_i$  curves. Prior to chlorophyll  
**2020** extraction, I used a cork borer to punch between 3 and 5 0.6  $\text{cm}^2$  disks from the  
**2021** leaf. Separate images of each punched leaf and set of leaf disks were curated using  
**2022** a flat-bed scanner to determine wet leaf area, again quantified using the ‘LeafArea’

**2023** R package (Katabuchi 2015). The punched leaf was dried and weighed after at  
**2024** least 65°C in the drying oven to determine  $M_{\text{area}}$  of the chlorophyll leaf.

**2025** Leaf disks were shuttled into a test tube containing 10mL dimethyl sulfoxide, vortexed, and incubated at 65°C for 120 minutes (Barnes et al. 1992). Incubated test tubes were vortexed again before loaded in 150  $\mu\text{L}$  triplicate aliquots to a 96-well plate. Dimethyl sulfoxide was also loaded in a 150  $\mu\text{L}$  triplicate aliquot as a blank. Absorbance measurements at 649.1 nm ( $A_{649.1}$ ) and 665.1 nm ( $A_{665.1}$ ) were read in each well using a plate reader (Biotek Synergy H1; Biotek Instruments, Winooski, VT USA) (Wellburn 1994), with triplicates subsequently averaged and corrected by the mean of the blank absorbance value. Blank-corrected absorbance values were used to estimate  $Chl_a$  ( $\mu\text{g mL}^{-1}$ ) and  $Chl_b$  ( $\mu\text{g mL}^{-1}$ ) following equations from Wellburn (1994):

$$Chl_a = 12.47A_{665.1} - 3.62A_{649.1} \quad (5.1)$$

**2035** and

$$Chl_b = 25.06A_{665.1} - 6.50A_{649.1} \quad (5.2)$$

**2036**  $Chl_a$  and  $Chl_b$  were converted to mmol  $\text{mL}^{-1}$  using the molar mass of chlorophyll a (893.51 g  $\text{mol}^{-1}$ ) and the molar mass of chlorophyll b (907.47 g  $\text{mol}^{-1}$ ), then added together to calculate total chlorophyll content in the dimethyl sulfoxide extractant (mmol  $\text{mL}^{-1}$ ). Total chlorophyll content was multiplied by the volume of the dimethyl sulfoxide extractant (10 mL) and converted to area-based chlorophyll content by dividing by the total area of the leaf disks ( $Chl_{\text{area}}$ ; mmol  $\text{m}^{-2}$ ). Mass-based chlorophyll content ( $Chl_{\text{mass}}$ ; mmol  $\text{g}^{-1}$ ) was calculated by dividing  $Chl_{\text{area}}$

**2043** by the leaf mass per area of the punched leaf.

**2044** 5.2.5 *A/C<sub>i</sub> curve fitting and parameter estimation*

**2045** I fit  $A_{\text{net}}/C_i$  curves of each individual using the ‘fitaci’ function in the ‘plantecophys’ R package (Duursma 2015). This function estimates the maximum rate  
**2046** of Rubisco carboxylation ( $V_{\text{cmax}}$ ;  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ) and maximum rate of electron  
**2047** transport for RuBP regeneration ( $J_{\text{max}}$ ;  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ) based on the Farquhar  
**2048** biochemical model of C<sub>3</sub> photosynthesis (Farquhar et al. 1980). Triose phosphate  
**2049** utilization (TPU) limitation was included in all curve fits, and all curve fits in-  
**2050** cluded measured dark respiration values. As  $A_{\text{net}}/C_i$  curves were generated using  
**2051** a common leaf temperature, curves were fit using Michaelis-Menten coefficients  
**2052** for Rubisco affinity to CO<sub>2</sub> ( $K_c$ ;  $\mu\text{mol mol}^{-1}$ ) and O<sub>2</sub> ( $K_o$ ;  $\mu\text{mol mol}^{-1}$ ), and the  
**2053** CO<sub>2</sub> compensation point ( $\Gamma^*$ ;  $\mu\text{mol mol}^{-1}$ ) reported in Bernacchi et al. (2001).  
**2054** Specifically,  $K_c$  was set to 404.9  $\mu\text{mol mol}^{-1}$ ,  $K_o$  was set to 278.4  $\mu\text{mol mol}^{-1}$ ,  
**2055** and  $\Gamma^*$  was set to 42.75  $\mu\text{mol mol}^{-1}$ . All curve fits were visually examined for  
**2056** goodness-of-fit. The use of a common leaf temperature across curves and dark  
**2057** respiration measurements eliminated the need to temperature standardize rate  
**2058** estimates. For clarity, I reference  $V_{\text{cmax}}$ ,  $J_{\text{max}}$ , and  $R_d$  estimates throughout the  
**2059** rest of the chapter as  $V_{\text{cmax25}}$ ,  $J_{\text{max25}}$ , and  $R_{d25}$ .

**2061** 5.2.6 *Stomatal limitation*

**2062** I quantified the extent by which stomatal conductance limited photosynthesis (l;  
**2063** unitless) following equations originally described in Farquhar and Sharkey (1982).  
**2064** Stomatal limitation was calculated as:

$$l = 1 - \frac{A_{net}}{A_{mod}} \quad (5.3)$$

**2065** where  $A_{mod}$  represents the photosynthetic rate where  $C_i=C_a$ .  $A_{mod}$  was calculated

**2066** as:

$$A_{mod} = V_{cmax25} - \frac{420 - \Gamma^*}{420 + K_m} - R_{d25} \quad (5.4)$$

**2067**  $K_m$  is the Michaelis-Menten coefficient for Rubisco-limited photosynthesis, calcu-

**2068** lated as:

$$K_m = K_c \cdot \left(1 + \frac{O_i}{K_o}\right) \quad (5.5)$$

**2069** where  $O_i$  refers to leaf intercellular  $O_2$  concentrations, set to  $210 \mu\text{mol mol}^{-1}$ .

**2070** 5.2.7 *Proportion of leaf nitrogen allocated to photosynthesis and structure*

**2071** I used equations from Niinemets and Tenhunen (1997) to estimate the proportion

**2072** of leaf nitrogen content allocated to Rubisco, bioenergetics, and light harvesting

**2073** proteins. The proportion of leaf nitrogen allocated to Rubisco ( $\rho_{rubisco}$ ;  $\text{gN gN}^{-1}$ )

**2074** was calculated as a function of  $V_{cmax25}$  and  $N_{area}$ :

$$\rho_{rubisco} = \frac{V_{cmax25} N_r}{V_{cr} N_{area}} \quad (5.6)$$

**2075** where  $N_r$  is the amount of nitrogen in Rubisco, set to  $0.16 \text{ gN}$  ( $\text{gN}$  in Rubisco) $^{-1}$

**2076** and  $V_{cr}$  is the maximum rate of RuBP carboxylation per unit Rubisco protein,

**2077** set to  $20.5 \mu\text{mol CO}_2 (\text{g Rubisco})^{-1}$ . The proportion of leaf nitrogen allocated to

**2078** bioenergetics ( $\rho_{bioe}$ ;  $\text{gN gN}^{-1}$ ) was similarly calculated as a function of  $J_{max25}$  and

**2079**  $N_{\text{area}}$ :

$$\rho_{\text{bioe}} = \frac{J_{\text{max}25} N_b}{J_{\text{mc}} N_{\text{area}}} \quad (5.7)$$

**2080** where  $N_b$  is the amount of nitrogen in cytochrome f, set to 0.12407 gN ( $\mu\text{mol}$   
**2081** cytochrome f) $^{-1}$  assuming a constant 1: 1: 1.2 cytochrome f: ferredoxin NADP  
**2082** reductase: coupling factor molar ratio (Evans and Seemann 1989; Niinemets and  
**2083** Tenhunen 1997), and  $J_{\text{mc}}$  is the capacity of electron transport per cytochrome f,  
**2084** set to 156  $\mu\text{mol}$  electron ( $\mu\text{mol}$  cytochrome f) $^{-1}\text{s}^{-1}$ .

**2085** The proportion of leaf nitrogen allocated to light harvesting proteins ( $\rho_{\text{light}}$ ;  
**2086** gN gN $^{-1}$ ) was calculated as a function of  $Chl_{\text{mass}}$  and  $N_{\text{mass}}$ :

$$\rho_{\text{light}} = \frac{Chl_{\text{mass}}}{N_{\text{mass}} c_b} \quad (5.8)$$

**2087** where  $c_b$  is the stoichiometry of the light-harvesting chlorophyll complexes of  
**2088** photosystem II, set to 2.75 mmol chlorophyll (gN in chlorophyll) $^{-1}$ . I used the  
**2089**  $N_{\text{mass}}$  value of the focal leaf used to generate  $A_{\text{net}}/C_i$  curves instead of the leaf  
**2090** used to extract chlorophyll content, as the two leaves are from the same trifoliolate  
**2091** leaf set and are highly correlated (Figure D1).

**2092** The proportion of leaf nitrogen content allocated to photosynthetic tissue  
**2093** ( $\rho_{\text{photo}}$ ; gN gN $^{-1}$ ) was estimated as the sum of  $\rho_{\text{rubisco}}$ ,  $\rho_{\text{bioe}}$ , and  $\rho_{\text{light}}$ . Finally,  
**2094** the proportion of leaf nitrogen content allocated to structural tissue ( $\rho_{\text{structure}}$ ; gN  
**2095** gN $^{-1}$ ) was estimated as:

$$\rho_{\text{structure}} = \frac{N_{\text{cw}}}{N_{\text{area}}} \quad (5.9)$$

**2096** where  $N_{\text{cw}}$  is the leaf nitrogen content allocated to cell walls (gN m $^{-2}$ ), calculated

2097 as a function of  $M_{area}$  using an empirical equation from Onoda et al. (2017):

$$N_{cw} = 0.000355 * M_{area}^{1.39} \quad (5.10)$$

2098 5.2.8 *Whole plant traits*

2099 Seven weeks after experiment initiation and immediately following gas exchange  
2100 measurements, I harvested all experimental individuals and separated biomass of  
2101 each experimental individual into major organ types (leaves, stems, roots, and  
2102 nodules when present). Fresh leaf area of all harvested leaves was measured using  
2103 an LI-3100C (Li-COR Biosciences, Lincoln, Nebraska, USA). Total fresh leaf area  
2104 ( $\text{cm}^2$ ) was calculated as the sum of all leaf areas, including the focal leaf used to  
2105 collect gas exchange data and the focal leaf used to extract chlorophyll content. All  
2106 harvested material was dried in an oven set to 65°C for at least 48 hours, weighed,  
2107 and ground to homogeneity. Leaves and nodules were manually ground with a  
2108 mortar and pestle, while stems and roots were ground using a Wiley mill (E3300  
2109 Mini Mill; Eberbach Corp., MI, USA). Total dry biomass (g) was calculated as  
2110 the sum of dry leaf (including focal leaf for both the  $A_{net}/C_i$  curve and leaf used  
2111 to extract chlorophyll content), stem, root, and root nodule biomass. I quantified  
2112 carbon and nitrogen content of each respective organ type through elemental  
2113 combustion (Costech-4010, Costech, Inc., Valencia, CA, USA) using subsamples  
2114 of ground and homogenized organ tissue.

2115 Following the approach explained in the first experimental chapter, I calcu-  
2116 lated structural carbon costs to acquire nitrogen as the ratio of total belowground  
2117 carbon biomass to whole plant nitrogen biomass ( $N_{cost}$ ;  $\text{gC gN}^{-1}$ ). Belowground

**2118** carbon biomass ( $C_{bg}$ ; gC) was calculated as the sum of root carbon biomass  
**2119** and root nodule carbon biomass. Root carbon biomass and root nodule carbon  
**2120** biomass was calculated as the product of the organ biomass and the respective  
**2121** organ carbon content. Whole plant nitrogen biomass ( $N_{wp}$ ; gN) was similarly  
**2122** calculated as the sum of total leaf, stem, root, and root nodule nitrogen biomass,  
**2123** including the focal leaf used for  $A_{net}/C_i$  curve and chlorophyll extractions. Leaf,  
**2124** stem, root, and root nodule nitrogen biomass was calculated as the product of  
**2125** the organ biomass and the respective organ nitrogen content. This calculation  
**2126** only quantifies plant structural carbon costs to acquire nitrogen and does not  
**2127** include any additional costs of nitrogen acquisition associated with respiration,  
**2128** root exudation, or root turnover. An explicit explanation of the limitations for  
**2129** interpreting this calculation can be found in Perkowski et al. (2021) and Terrer  
**2130** et al. (2018).

**2131** Finally, plant investments in nitrogen fixation were calculated as the ratio  
**2132** of root nodule biomass to root biomass, where increasing values indicate an in-  
**2133** crease in plant investments to nitrogen fixation (Dovrat et al. 2018; Dovrat et al.  
**2134** 2020; Perkowski et al. 2021). I also calculated the percent of leaf nitrogen ac-  
**2135** quired from the atmosphere ( $\%N_{dfa}$ ; %) using leaf  $\delta^{15}\text{N}$  and the following equation  
**2136** from Andrews et al. (2011):

$$\%N_{dfa} = \frac{\delta^{15}\text{N}_{reference} - \delta^{15}\text{N}_{sample}}{\delta^{15}\text{N}_{reference} - B} \quad (5.11)$$

**2137** where  $\delta^{15}\text{N}_{reference}$  refers to a reference plant that exclusively acquires nitrogen via  
**2138** direct uptake,  $\delta^{15}\text{N}_{sample}$  refers to an individual's leaf  $\delta^{15}\text{N}$ , and B refers to indi-

2139 individuals that are entirely reliant on nitrogen fixation. Within each unique nitrogen  
2140 fertilization treatment-by-CO<sub>2</sub> treatment combination, I calculated the mean leaf  
2141 δ<sup>15</sup>N for individuals growing in the non-inoculated treatment for δ<sup>15</sup>N<sub>reference</sub>. Any  
2142 individuals with visual confirmation of root nodule formation were omitted from  
2143 the calculation of δ<sup>15</sup>N<sub>reference</sub>. Following recommendations from Andrews et al.  
2144 (2011) I calculated B within each CO<sub>2</sub> treatment using the mean leaf δ<sup>15</sup>N of  
2145 inoculated individuals that received 0 ppm N. I did not calculate B within each  
2146 unique soil nitrogen-by-CO<sub>2</sub> treatment combination, as previous studies suggest  
2147 decreased reliance on nitrogen fixation with increasing soil nitrogen availability  
2148 (Perkowski et al. 2021).

2149 5.2.9 *Statistical analyses*

2150 Uninoculated pots that had substantial root nodule formation (nodule biomass:  
2151 root biomass values greater than 0.05 g g<sup>-1</sup>) were removed from all analyses, as  
2152 pots were assumed to have been colonized by symbiotic nitrogen-fixing bacteria  
2153 from outside sources. This decision resulted in the removal of sixteen pots from  
2154 analyses: two pots in the elevated CO<sub>2</sub> treatment that received 35 ppm N, three  
2155 pots in the elevated CO<sub>2</sub> treatment that received 70 ppm N, one pot in the elevated  
2156 CO<sub>2</sub> treatment that received 210 ppm N, two pots in the elevated CO<sub>2</sub> treatment  
2157 that received 280 ppm N, two pots in the ambient CO<sub>2</sub> treatment that received  
2158 0 ppm N, three pots in the ambient CO<sub>2</sub> treatment that received 70 ppm N, two  
2159 pots in the ambient CO<sub>2</sub> treatment that received 105 ppm N, and one pot in the  
2160 ambient CO<sub>2</sub> treatment that received 280 ppm N.

2161 I built a series of linear mixed effects models to investigate the impacts of

2162 CO<sub>2</sub> concentration, soil nitrogen fertilization, and inoculation with *B. japonicum*  
2163 on *G. max* gas exchange, tradeoffs between nitrogen and water use, whole plant  
2164 growth, and investment in nitrogen fixation. All models included CO<sub>2</sub> treatment  
2165 as a categorical fixed effect, inoculation treatment as a categorical fixed effect,  
2166 soil nitrogen fertilization as a continuous fixed effect, with interaction terms be-  
2167 tween all three fixed effects. All models also accounted for climatic difference  
2168 between chambers across experiment iterations by including a random intercept  
2169 term that nested starting chamber rack by CO<sub>2</sub> treatment. Models with this  
2170 independent variable structure were created for each of the following dependent  
2171 variables:  $N_{\text{area}}$ ,  $M_{\text{area}}$ ,  $N_{\text{mass}}$ ,  $Chl_{\text{area}}$ ,  $V_{\text{cmax25}}$ ,  $J_{\text{max25}}$ ,  $J_{\text{max25}}:V_{\text{cmax25}}$ ,  $R_{\text{d25}}$ ,  $g_{\text{sw}}$ ,  
2172 stomatal limitation,  $\rho_{\text{rubisco}}$ ,  $\rho_{\text{bioe}}$ ,  $\rho_{\text{light}}$ ,  $\rho_{\text{photo}}$ ,  $\rho_{\text{structure}}$ , total biomass, total leaf  
2173 area,  $N_{\text{cost}}$ ,  $C_{\text{bg}}$ ,  $N_{\text{wp}}$ , nodule biomass, the ratio of nodule biomass to root biomass,  
2174 and % $N_{\text{dfa}}$ .

2175 I used Shapiro-Wilk tests of normality to determine whether linear mixed  
2176 effects models satisfied residual normality assumptions. If residual normality as-  
2177 sumptions were not met (Shapiro-Wilk:  $p < 0.05$ ), then models were fit using de-  
2178 pendent variables that were natural log transformed. If residual normality as-  
2179 sumptions were still not met (Shapiro-Wilk:  $p < 0.05$ ), then models were fit using  
2180 dependent variables that were square root transformed. All residual normality  
2181 assumptions that did not originally satisfy residual normality assumptions were  
2182 met with either a natural log or square root data transformation (Shapiro-Wilk:  
2183  $p > 0.05$  in all cases). Specifically, models for  $N_{\text{area}}$ ,  $N_{\text{mass}}$ ,  $Chl_{\text{area}}$ ,  $V_{\text{cmax25}}$ ,  $J_{\text{max25}}$ ,  
2184  $J_{\text{max25}}:V_{\text{cmax25}}$ ,  $R_{\text{d25}}$ ,  $g_{\text{sw}}$ , stomatal limitation,  $\rho_{\text{rubisco}}$ ,  $\rho_{\text{bioe}}$ ,  $\rho_{\text{light}}$ ,  $\rho_{\text{photo}}$ , total leaf  
2185 area,  $N_{\text{cost}}$  satisfied residual normality assumptions without data transformation.

2186 Models for  $M_{\text{area}}$ ,  $\rho_{\text{structure}}$ ,  $C_{\text{bg}}$ , and total biomass satisfied residual normality as  
2187 assumptions with a natural log data transformation, while models for  $N_{\text{wp}}$ , nodule  
2188 biomass, nodule biomass: root biomass, and  $\%N_{\text{dfa}}$  satisfied residual normality  
2189 assumptions with a square root data transformation.

2190 In all statistical models, I used the ‘lmer’ function in the ‘lme4’ R package  
2191 (Bates et al. 2015) to fit each model and the ‘Anova’ function in the ‘car’ R  
2192 package (Fox and Weisberg 2019) to calculate Type II Wald’s  $\chi^2$  and determine  
2193 the significance ( $\alpha=0.05$ ) of each fixed effect coefficient. I used the ‘emmeans’  
2194 R package (Lenth 2019) to conduct post-hoc comparisons using Tukey’s tests,  
2195 where degrees of freedom were approximated using the Kenward-Roger approach  
2196 (Kenward and Roger 1997). All analyses and plots were conducted in R version  
2197 4.2.0 (R Core Team 2021).

2198 5.3 Results

2199 5.3.1 Leaf nitrogen and chlorophyll content

2200 Elevated CO<sub>2</sub> reduced  $N_{\text{area}}$ ,  $N_{\text{mass}}$ , and  $Chl_{\text{area}}$  by 29%, 50%, and 31%, respec-  
2201 tively, and stimulated  $M_{\text{area}}$  by 44% ( $p<0.001$  in all cases; Table 5.1). An inter-  
2202 action between fertilization and CO<sub>2</sub> (CO<sub>2</sub>-by-fertilization interaction:  $p_{N_{\text{area}}}=$   
2203 0.017,  $p_{N_{\text{mass}}}<0.001$ ,  $p_{Chl_{\text{area}}}=0.083$ ; Table 5.1) indicated that the positive effect  
2204 of increasing fertilization on  $N_{\text{area}}$ ,  $N_{\text{mass}}$ , and  $Chl_{\text{area}}$  ( $p<0.001$  in all cases; Table  
2205 5.1) was stronger under ambient CO<sub>2</sub> (Tukey <sub>$N_{\text{area}}$</sub> :  $p=0.026$ ; Tukey <sub>$N_{\text{mass}}$</sub> :  $p<0.001$ ;  
2206 Tukey <sub>$Chl_{\text{area}}$</sub> :  $p=0.065$ ; Table 5.1; Figs. 5.1a, 5.1b, 5.1d). An interaction between  
2207 fertilization and CO<sub>2</sub> on  $M_{\text{area}}$  (CO<sub>2</sub>-by-fertilization interaction:  $p=0.006$ ; Ta-  
2208 ble 5.1) indicated that the positive effect of increasing fertilization on  $M_{\text{area}}$  was

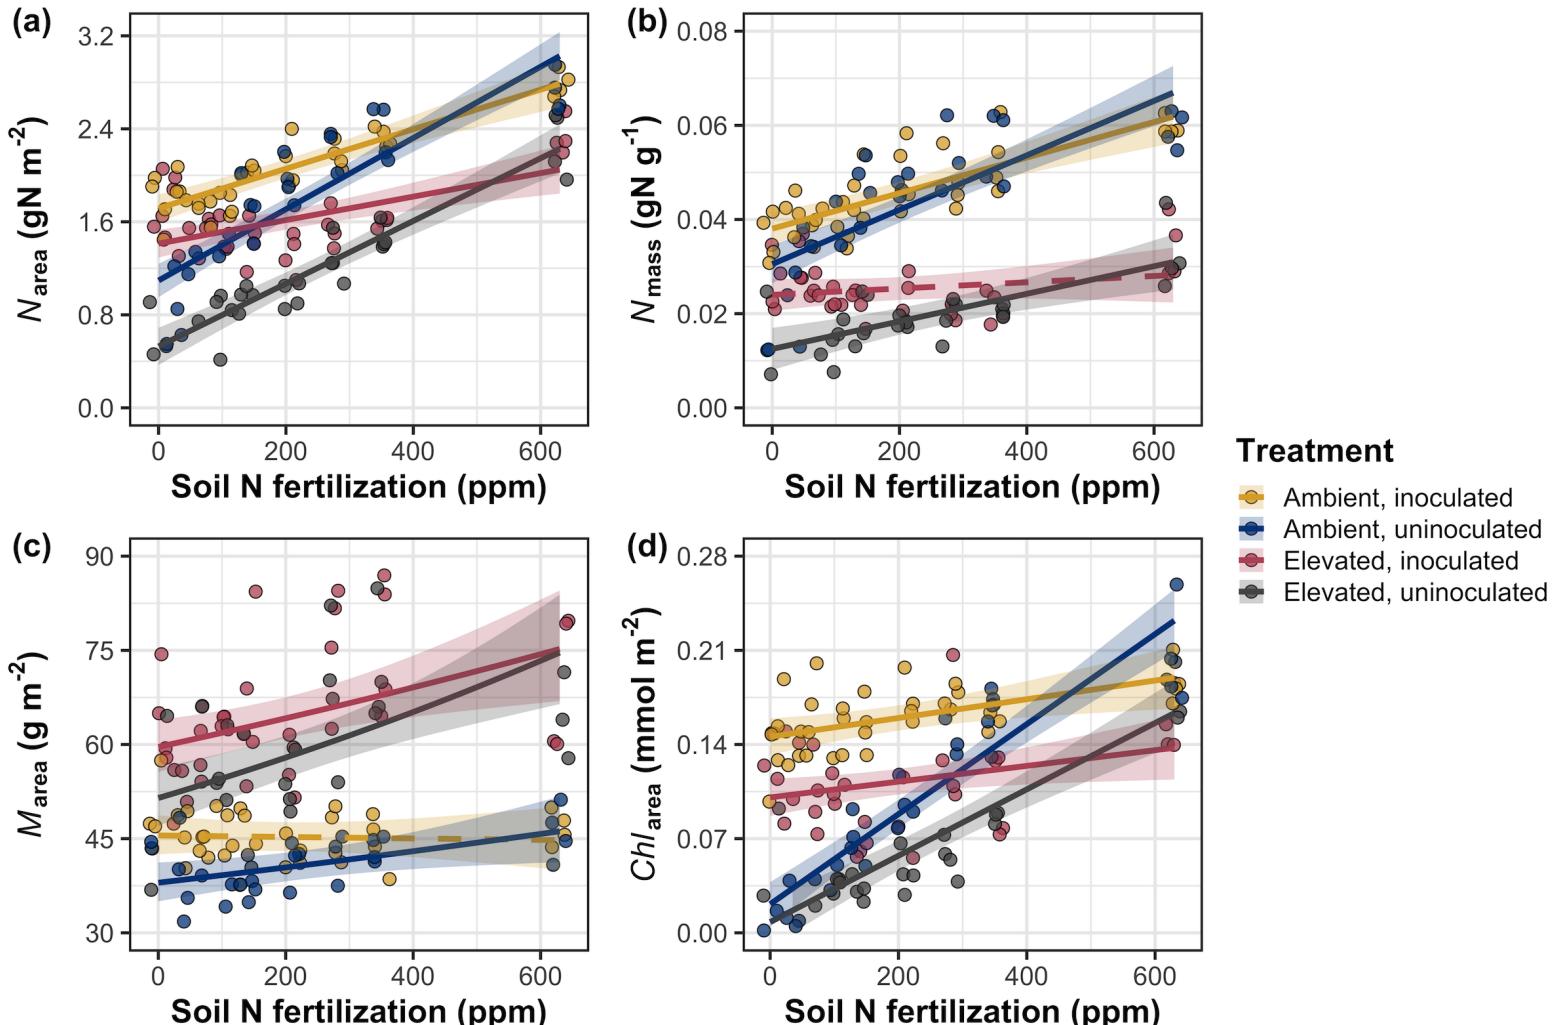

**2209** stronger under elevated CO<sub>2</sub> (Tukey:  $p=0.009$ ; Fig. 5.1c). Overall, interactions  
**2210** between fertilization and CO<sub>2</sub> resulted in stronger reductions in  $N_{\text{area}}$ ,  $N_{\text{mass}}$ , and  
**2211**  $Chl_{\text{area}}$ , and a stronger stimulation in  $M_{\text{area}}$  under elevated CO<sub>2</sub> with increasing  
**2212** fertilization.

**2213** An interaction between inoculation and CO<sub>2</sub> on  $N_{\text{area}}$  (CO<sub>2</sub>-by-inoculation  
**2214** interaction:  $p=0.030$ ; Table 5.1) indicated that the positive effect of inoculation  
**2215** on  $N_{\text{area}}$  ( $p<0.001$ ; Table 5.1) was stronger under elevated CO<sub>2</sub> (45% increase;  
**2216** Tukey:  $p<0.001$ ) than under ambient CO<sub>2</sub> (18% increase; Tukey:  $p<0.001$ ), a  
**2217** result that increased the reduction in  $N_{\text{area}}$  in inoculated pots under elevated  
**2218** CO<sub>2</sub>. Inoculation treatment did not modify the reduction in  $N_{\text{mass}}$  (CO<sub>2</sub>-by-  
**2219** inoculation interaction:  $p=0.148$ ; Table 5.1) and  $Chl_{\text{area}}$  ( $p = 0.147$ ; Table 5.1)  
**2220** or the stimulation in  $M_{\text{area}}$  ( $p=0.866$ ; Table 5.1) under elevated CO<sub>2</sub>. How-  
**2221** ever, interactions between fertilization and inoculation on  $N_{\text{area}}$ ,  $N_{\text{mass}}$ ,  $M_{\text{area}}$ ,  
**2222** and  $Chl_{\text{area}}$  (fertilization-by-inoculation interaction:  $p_{N_{\text{area}}}<0.001$ ,  $p_{N_{\text{mass}}}=0.001$ ,  
**2223**  $p_{M_{\text{area}}}=0.025$ ,  $p_{Chl_{\text{area}}}=0.083$ ; Table 5.1) indicated that the positive effect of in-  
**2224** creasing fertilization on each trait was stronger in uninoculated pots (Tukey $N_{\text{area}}$ :  
**2225**  $p<0.001$ ; Tukey $N_{\text{mass}}$ :  $p=0.001$ ; Tukey $M_{\text{area}}$ :  $p=0.031$ ; Tukey $Chl_{\text{area}}$ :  $p<0.001$ ;  
**2226** Figs. 5.1a-d).

**Table 5.1.** Effects of soil nitrogen fertilization, inoculation, and CO<sub>2</sub> treatments on leaf nitrogen content per unit leaf area ( $N_{\text{area}}$ ; gN m<sup>-2</sup>), leaf nitrogen content per unit leaf mass ( $N_{\text{mass}}$ , gN g<sup>-1</sup>), leaf mass per unit leaf area ( $M_{\text{area}}$ ; g m<sup>-2</sup>), and chlorophyll content per unit leaf area ( $Chl_{\text{area}}$ ; mmol m<sup>-2</sup>)<sup>\*</sup>

2227 \*Significance determined using Type II Wald  $\chi^2$  tests ( $\alpha=0.05$ ). P-values less than 0.05 are in bold, while p-values  
 2228 between 0.05 and 0.1 are italicized. A superscript “a” is included after trait labels to indicate if models were fit with  
 2229 natural log transformed response variables. Key: df=degrees of freedom,  $\chi^2$ =Wald Type II chi-square test statistic.

**Figure 5.1.** Effects of  $\text{CO}_2$ , fertilization, and inoculation on leaf nitrogen per unit leaf area (a), leaf nitrogen content (b), leaf mass per unit leaf area (c), and chlorophyll content per unit leaf area (d). Soil nitrogen fertilization is represented on the x-axis in all panels. Yellow points and trendlines indicate inoculated individuals grown under ambient  $\text{CO}_2$ , blue points and trendlines indicate uninoculated individuals grown under ambient  $\text{CO}_2$ , red points and trendlines indicate inoculated individuals grown under elevated  $\text{CO}_2$ , and gray points indicate uninoculated individuals grown under elevated  $\text{CO}_2$ . Solid trendlines indicate regression slopes that are different from zero

**2230** 5.3.2 *Leaf biochemistry and stomatal conductance*

**2231** Elevated CO<sub>2</sub> resulted in plants with 16% lower  $V_{cmax25}$  ( $p<0.001$ ; Table 5.2) and  
**2232** 10% lower  $J_{max25}$  ( $p=0.014$ ; Table 5.2) compared to those grown under ambient  
**2233** CO<sub>2</sub>. However, CO<sub>2</sub> concentration did not influence  $R_{d25}$  ( $p=0.613$ ; Table 5.2;  
**2234** Fig. 5.2d). A relatively stronger reduction in  $V_{cmax25}$  than  $J_{max25}$  resulted in  
**2235** an 8% stimulation in  $J_{max25}:V_{cmax25}$  under elevated CO<sub>2</sub> ( $p<0.001$ ; Table 5.2).  
**2236** The negative effect of CO<sub>2</sub> on  $V_{cmax25}$  and  $J_{max25}$  was not modified across the  
**2237** fertilization gradient (CO<sub>2</sub>-by-fertilization interaction:  $p=0.185$  and  $p=0.389$  for  
**2238**  $V_{cmax25}$  and  $J_{max25}$ , respectively; Table 5.2; Figs. 5.2a, 5.2b) or between inocula-  
**2239** tion treatments (CO<sub>2</sub>-by-inoculation interaction:  $p=0.799$  and  $p=0.714$  for  $V_{cmax25}$   
**2240** and  $J_{max25}$ , respectively; Table 5.2). However, a strong interaction between fer-  
**2241** tilization and inoculation (fertilization-by-inoculation interaction:  $p\leq0.001$  in all  
**2242** cases; Table 5.2) indicated that the positive effect of increasing fertilization on  
**2243**  $V_{cmax25}$  ( $p<0.001$ ; Table 5.2),  $J_{max25}$  ( $p<0.001$ ; Table 5.2), and  $R_{d25}$  ( $p=0.015$ ;  
**2244** Table 5.2) was only observed in uninoculated pots (Tukey:  $p\leq0.001$  in all cases;  
**2245** Figs. 5.2a, 5.2b). A stronger positive effect of increasing fertilization on  $V_{cmax25}$   
**2246** than  $J_{max25}$  resulted in a reduction in  $J_{max25}:V_{cmax25}$  with increasing fertilization  
**2247** ( $p<0.001$ ; Table 5.2), though this pattern was only observed in uninoculated pots  
**2248** (fertilization-by-inoculation interaction:  $p=0.002$ ; Table 5.2; Fig. 5.2c).  
  
**2249** Elevated CO<sub>2</sub> reduced stomatal conductance by 20% ( $p<0.001$ ; Table 5.2;  
**2250** Fig. 5.2e), but this pattern did not influence stomatal limitation of photosyn-  
**2251** thesis ( $p=0.355$ ; Table 5.2; Fig. 5.2f). As with  $V_{cmax25}$  and  $J_{max25}$ , the reduction  
**2252** in stomatal conductance under elevated CO<sub>2</sub> was not modified across the fertil-  
**2253** ization gradient (CO<sub>2</sub>-by-fertilization interaction:  $p=0.141$ ; Table 5.2) or between

**2254** inoculation treatments ( $\text{CO}_2$ -by-inoculation interaction:  $p=0.179$ ; Table 5.2). Fer-  
**2255**tilization did not modify the null effect of  $\text{CO}_2$  on stomatal limitation ( $\text{CO}_2$ -by-  
**2256**fertilization interaction:  $p=0.554$ ; Table 5.2). An interaction between  $\text{CO}_2$  and  
**2257**inoculation ( $\text{CO}_2$ -by-inoculation interaction:  $p=0.043$ ; Table 5.2) indicated that  
**2258**inoculation increased stomatal limitation under ambient  $\text{CO}_2$  (Tukey:  $p=0.021$ ),  
**2259**but not under elevated  $\text{CO}_2$  (Tukey:  $p>0.999$ ). An additional interaction between  
**2260**inoculation and fertilization on stomatal conductance (fertilization-by-inoculation  
**2261**interaction:  $p<0.001$ ; Table 5.2) indicated that increasing fertilization increased  
**2262**stomatal conductance in uninoculated pots (Tukey:  $p=0.003$ ) but decreased stom-  
**2263**atal conductance in inoculated pots (Tukey:  $p=0.021$ ). The similar in magnitude,  
**2264**but opposite direction, trend in the effect of increasing fertilization on stomatal  
**2265**conductance between inoculation treatments likely drove a null response of stom-  
**2266**atal conductance to increasing fertilization ( $p=0.642$ ; Table 5.2).

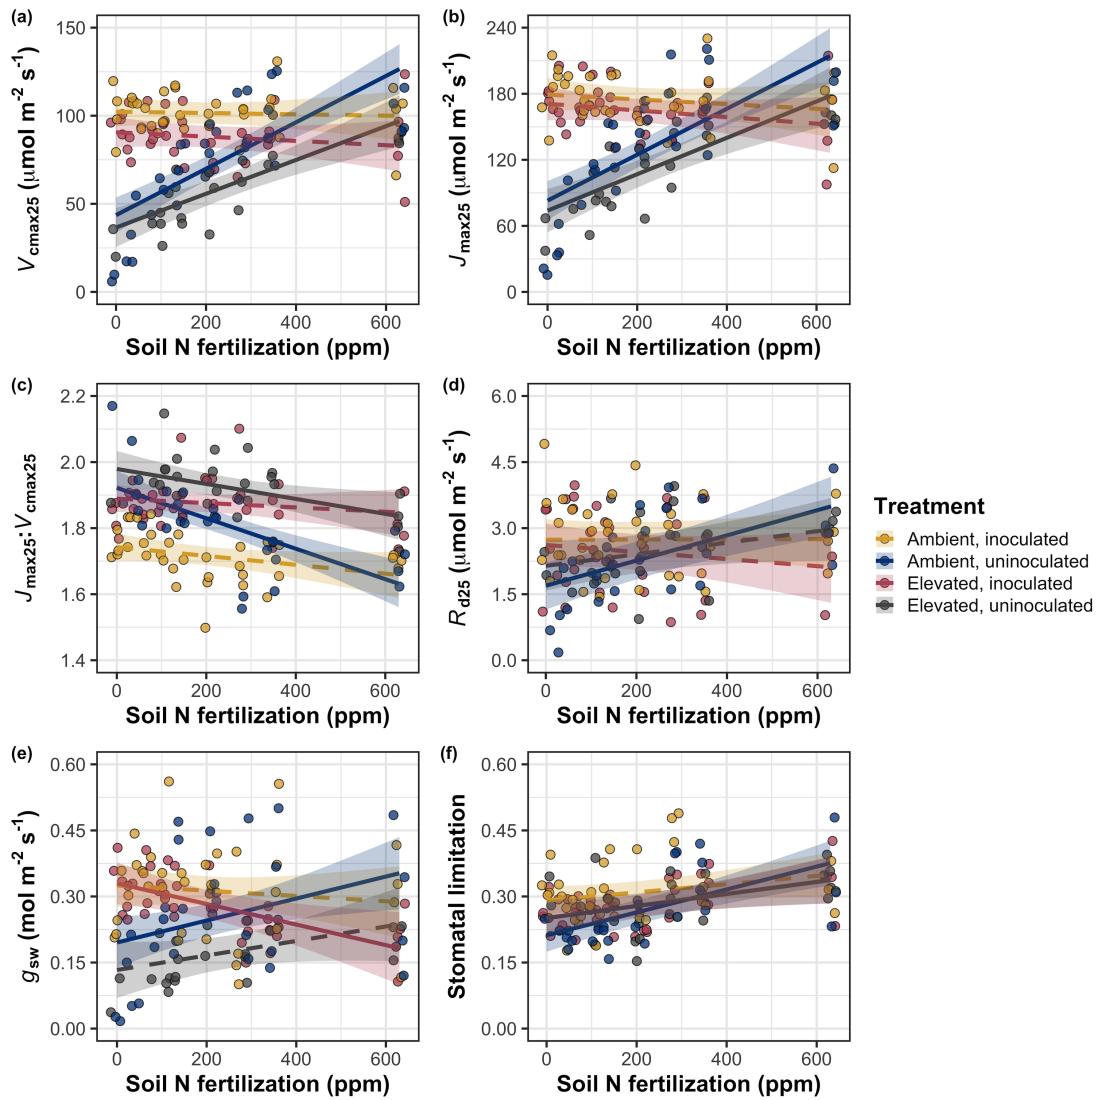

**Table 5.2.** Effects of soil nitrogen fertilization, inoculation, and CO<sub>2</sub> on the maximum rate of Rubisco carboxylation ( $V_{\text{cmax}25}$ ;  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ), the maximum rate of RuBP regeneration ( $J_{\text{max}25}$ ;  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ), dark respiration ( $R_{\text{d}25}$ ;  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ), the ratio of the maximum rate of RuBP regeneration to the maximum rate of Rubisco carboxylation ( $J_{\text{max}25}:V_{\text{cmax}25}$ ; unitless), stomatal conductance ( $g_{\text{sw}}$ ;  $\text{mol m}^{-2} \text{s}^{-1}$ ), and stomatal limitation (unitless)\*

2267 \*Significance determined using Type II Wald  $\chi^2$  tests ( $\alpha=0.05$ ). P-values less than 0.05 are in bold, while p-values  
 2268 between 0.05 and 0.1 are italicized. Key: df=degrees of freedom;  $\chi^2$ =Wald Type II chi-square test statistic.

**Figure 5.2.** Effects of  $\text{CO}_2$ , fertilization, and inoculation on maximum rate of Rubisco carboxylation (a), the maximum rate of RuBP regeneration (b), and the ratio of the maximum rate of RuBP regeneration to the maximum rate of Rubisco carboxylation leaf mass per unit leaf area (c), dark respiration (d), stomatal conductance (e), and stomatal limitation (f). Soil nitrogen fertilization is represented on the x-axis in all panels. Colored points and trendlines are as explained in Figure 5.1.

**2269** 5.3.3 *Leaf nitrogen allocation*

**2270** A relatively stronger reduction in  $N_{\text{area}}$  than  $V_{\text{cmax25}}$  and  $J_{\text{max25}}$  under elevated  
**2271**  $\text{CO}_2$  resulted in an 20% and 29% respective increase in  $\rho_{\text{rubisco}}$  and  $\rho_{\text{bioe}}$  ( $p<0.001$   
**2272** in both cases; Table 5.3). There was no effect of  $\text{CO}_2$  on  $\rho_{\text{light}}$  ( $p=0.700$ ; Table  
**2273** 5.3), but the increase in  $\rho_{\text{rubisco}}$  and  $\rho_{\text{bioe}}$  resulted in 21% greater  $\rho_{\text{photo}}$  under  
**2274** elevated  $\text{CO}_2$  ( $p<0.001$ ; Table 5.3; Fig. 5.3a). Effects of  $\text{CO}_2$  on  $\rho_{\text{rubisco}}$ ,  $\rho_{\text{bioe}}$ ,  
**2275** and  $\rho_{\text{photo}}$  were not modified across the fertilization gradient ( $\text{CO}_2$ -by-fertilization  
**2276** interaction:  $p_{\text{rubisco}}=0.269$ ,  $p_{\text{bioe}}=0.298$ ,  $p_{\text{photo}}=0.281$ ; Table 5.3). A marginal in-  
**2277** teraction between inoculation and  $\text{CO}_2$  on  $\rho_{\text{rubisco}}$  and  $\rho_{\text{photo}}$  ( $\text{CO}_2$ -by-inoculation  
**2278** interaction:  $p_{\text{rubisco}}=0.057$ ,  $p_{\text{photo}}=0.055$ ; Table 5.3) indicated that the positive ef-  
**2279** fect of inoculation on  $\rho_{\text{rubisco}}$  and  $\rho_{\text{photo}}$  ( $p<0.001$  in both cases; Table 5.3) was only  
**2280** apparent under ambient  $\text{CO}_2$  (Tukey:  $p<0.001$  in both cases). Inoculation did  
**2281** not modify the positive effect of elevated  $\text{CO}_2$  on  $\rho_{\text{bioe}}$  ( $\text{CO}_2$ -by-inoculation inter-  
**2282** action:  $p=0.122$ ; Table 5.3) or the null effect of  $\text{CO}_2$  on  $\rho_{\text{bioe}}$  ( $\text{CO}_2$ -by-inoculation  
**2283** interaction:  $p=0.298$ ; Table 5.3). An interaction between fertilization and inocula-  
**2284** tion on  $\rho_{\text{rubisco}}$ ,  $\rho_{\text{bioe}}$ , and  $\rho_{\text{photo}}$  (fertilization-by-inoculation interaction:  $p<0.001$   
**2285** in all cases; Table 5.3) indicated that the negative effect of increasing fertilization  
**2286** on each trait ( $p<0.001$  in all cases; Table 5.3) was only observed in inoculated pots  
**2287** (Tukey:  $p<0.001$  in all cases). An additional interaction between fertilization and  
**2288** inoculation on  $\rho_{\text{light}}$  (fertilization-by-inoculation interaction:  $p<0.001$ ; Table 5.3)  
**2289** indicated a negative effect of increasing fertilization on  $\rho_{\text{light}}$  in inoculated pots  
**2290** (Tukey:  $p=0.041$ ), but a positive effect of increasing fertilization in uninoculated  
**2291** pots (Tukey:  $p<0.001$ ).

**2292** Increased  $M_{\text{area}}$  under elevated  $\text{CO}_2$  resulted in an 133% stimulation of

**2293**  $\rho_{\text{structure}}$  ( $p<0.001$ ; Table 5.3; Fig 5.3b). An interaction between fertilization and  
**2294** CO<sub>2</sub> (CO<sub>2</sub>-by-fertilization interaction:  $p=0.039$ ; Table 5.3) indicated that the  
**2295** negative effect of increasing fertilization ( $p<0.001$ ; Table 5.3) on  $\rho_{\text{structure}}$  was  
**2296** marginally stronger under ambient CO<sub>2</sub> (Tukey:  $p=0.055$ ). A marginal inter-  
**2297** action between inoculation and CO<sub>2</sub> (CO<sub>2</sub>-by-inoculation interaction:  $p=0.057$ ;  
**2298** Table 5.3) indicated that the positive effect of inoculation on  $\rho_{\text{structure}}$  ( $p<0.001$ ;  
**2299** Table 5.3) was only observed under elevated CO<sub>2</sub> (Tukey:  $p<0.001$ ), with no ap-  
**2300** parent inoculation effect observed under ambient CO<sub>2</sub> (Tukey:  $p=0.513$ ). Finally,  
**2301** an interaction between fertilization and inoculation (fertilization-by-inoculation  
**2302** interaction:  $p<0.001$ ; Table 5.3) indicated that, while increasing fertilization in-  
**2303** creased  $\rho_{\text{structure}}$  ( $p<0.001$ ; Table 5.3), this response was stronger in uninoculated  
**2304** pots (Tukey:  $p=0.001$ ; Fig. 5.3b).

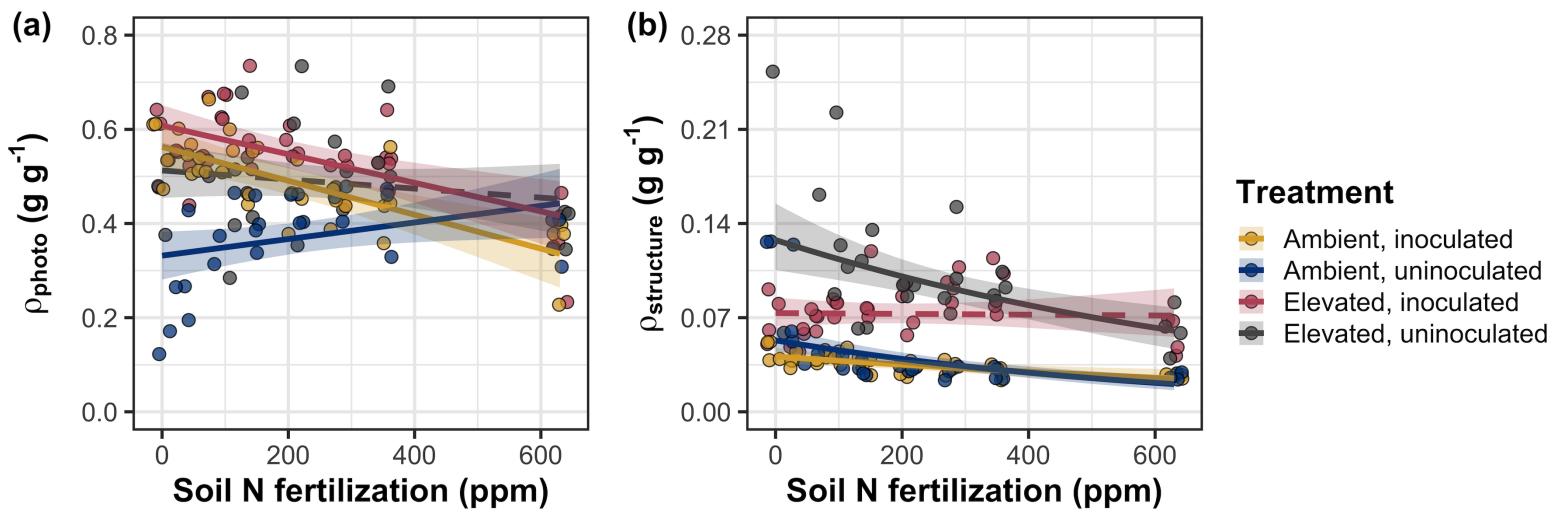

**Table 5.3.** Effects of soil nitrogen fertilization, inoculation, and CO<sub>2</sub> on the fraction of leaf nitrogen allocated to Rubisco ( $\rho_{\text{rubisco}}$ ; gN gN<sup>-1</sup>), bioenergetics ( $\rho_{\text{bioe}}$ ; gN gN<sup>-1</sup>), light harvesting proteins ( $\rho_{\text{light}}$ ; gN gN<sup>-1</sup>), photosynthesis ( $\rho_{\text{photo}}$ ; gN gN<sup>-1</sup>), and structure ( $\rho_{\text{structure}}$ ; gN gN<sup>-1</sup>)\*

2305 \*Significance determined using Type II Wald  $\chi^2$  tests ( $\alpha=0.05$ ). P-values less than 0.05 are in bold, while p-values  
 2306 between 0.05 and 0.1 are italicized. A superscript “a” is included after trait labels to indicate if models were fit with  
 2307 natural log transformed response variable. Key: df=degrees of freedom;  $\chi^2$ =Wald Type II chi-square test statistic.

**Figure 5.3.** Effects of  $\text{CO}_2$ , fertilization, and inoculation on the relative fraction of leaf nitrogen allocated to photosynthesis (a) and the fraction of leaf nitrogen allocated to structure (b). Soil nitrogen fertilization is represented on the x-axis in both panels. Colored points and trendlines are as explained in Figure 5.1.

**2308** 5.3.4 *Whole plant traits*

**2309** Total leaf area and total biomass were 51% and 102% greater under elevated CO<sub>2</sub>,  
**2310** respectively ( $p<0.001$  in both cases; Table 5.4). The stimulation in total leaf area  
**2311** and total biomass under elevated CO<sub>2</sub> was enhanced by increasing fertilization  
**2312** (CO<sub>2</sub>-by-fertilization interaction:  $p<0.001$  in both cases; Table 5.4; Figs. 5.4a,  
**2313** 5.4b) but was not modified across inoculation treatments (CO<sub>2</sub>-by-inoculation  
**2314** interaction:  $p_{total\_leaf\_area}=0.151$ ,  $p_{total\_biomass}=0.472$ ; Table 5.4). The positive  
**2315** effect of increasing fertilization on total leaf area and total biomass was modified by  
**2316** inoculation treatment (fertilization-by-inoculation interaction:  $p<0.001$  in both  
**2317** cases; Table 5.4), indicating a stronger positive effect of increasing fertilization in  
**2318** uninoculated pots (Tukey:  $p_{total\_leaf\_area}=0.002$ ,  $p_{total\_biomass}=0.001$ , Figs. 5.4a,  
**2319** 5.4b).

**2320** A 62% stimulation in  $N_{cost}$  under elevated CO<sub>2</sub> was modified through a  
**2321** strong three-way interaction between CO<sub>2</sub>, fertilization, and inoculation (CO<sub>2</sub>-  
**2322** by-inoculation-by-fertilization interaction:  $p<0.001$ ; Table 5.4; Fig. 5.4). This  
**2323** interaction revealed a general negative effect of increasing fertilization on  $N_{cost}$   
**2324** ( $p<0.001$ ; Table 5.4) that was observed in all treatment combinations (Tukey:  
**2325**  $p<0.001$  in all cases) except for inoculated pots grown under elevated CO<sub>2</sub> (Tukey:  
**2326**  $p=0.779$ ; Fig. 5.4c). This response also resulted in stronger negative effects of in-  
**2327** creasing fertilization on  $N_{cost}$  in uninoculated pots grown under elevated CO<sub>2</sub> than  
**2328** uninoculated pots grown under ambient CO<sub>2</sub> (Tukey:  $p=0.001$ ) and inoculated  
**2329** pots grown under either ambient CO<sub>2</sub> (Tukey:  $p<0.001$ ) or elevated CO<sub>2</sub> (Tukey:  
**2330**  $p<0.001$ ), while uninoculated pots grown under ambient CO<sub>2</sub> had stronger nega-  
**2331** tive effects of increasing fertilization on  $N_{cost}$  than inoculated pots grown under

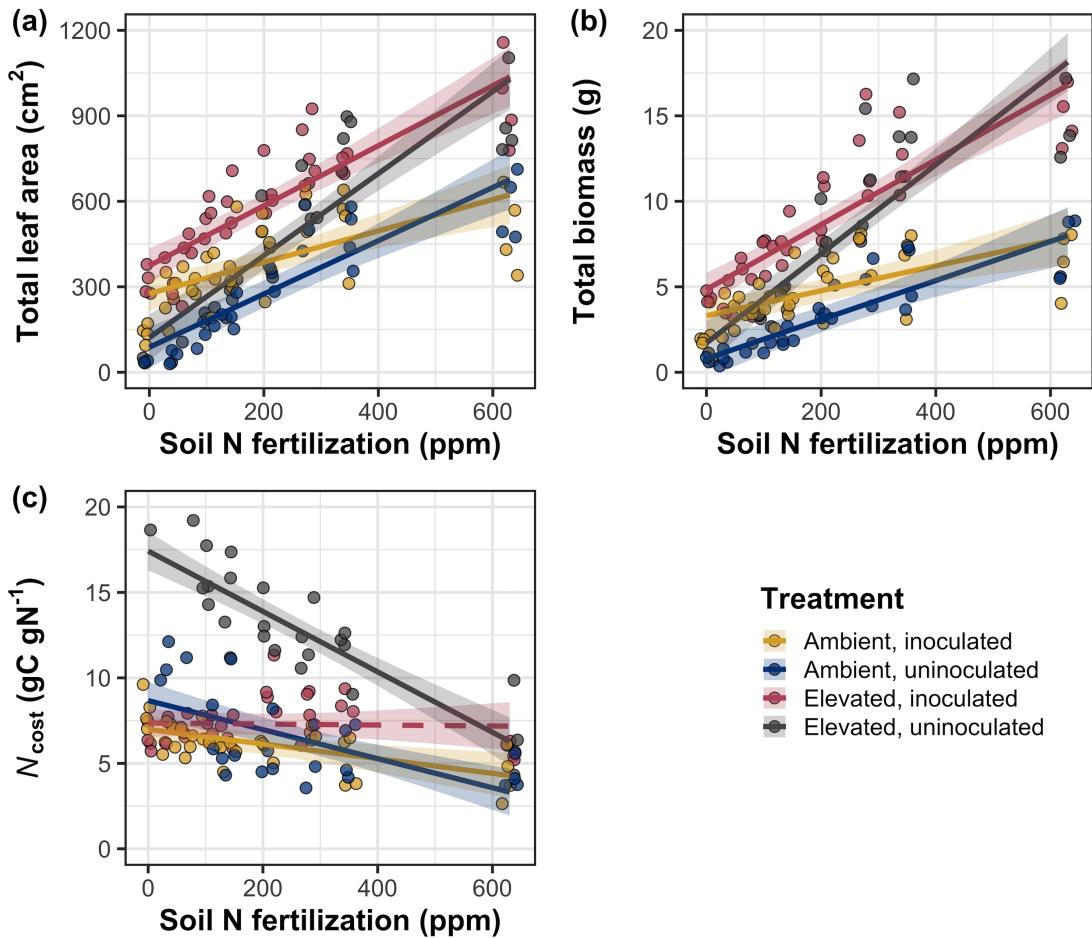

**2332** elevated CO<sub>2</sub> (Tukey:  $p=0.002$ ), but not inoculated pots grown under ambient  
**2333** CO<sub>2</sub> (Tukey:  $p=0.216$ ; Fig. 5.4). The reduction in  $N_{\text{cost}}$  with increasing fertiliza-  
**2334** tion and in uninoculated pots were driven by a stronger positive effect of increasing  
**2335** fertilization on  $N_{\text{wp}}$  (denominator of  $N_{\text{cost}}$ ) than  $C_{\text{bg}}$  (numerator of  $N_{\text{cost}}$ ), while  
**2336** the stimulation in  $N_{\text{cost}}$  under elevated CO<sub>2</sub> was driven by a stronger positive  
**2337** effect of elevated CO<sub>2</sub> on  $C_{\text{bg}}$  than  $N_{\text{wp}}$  (Table 5.4).

**Table 5.4.** Effects of CO<sub>2</sub>, fertilization, and inoculation on total leaf area (cm<sup>2</sup>), whole plant biomass (g), carbon costs to acquire nitrogen ( $N_{\text{cost}}$ ; gC gN<sup>-1</sup>), belowground carbon biomass ( $C_{\text{bg}}$ ; gC), and whole plant nitrogen biomass ( $N_{\text{wp}}$ ; gN)<sup>\*</sup>

2338 \*Significance determined using Type II Wald  $\chi^2$  tests ( $\alpha=0.05$ ). P-values less than 0.05 are in bold. Superscripts  
 2339 included after trait labels indicate if models were fit with natural log (<sup>a</sup>) or square root (<sup>b</sup>) transformed response  
 2340 variables. Key: df=degrees of freedom;  $\chi^2$ =Wald Type II chi-square test statistic.

**Figure 5.4.** Effects of  $\text{CO}_2$ , fertilization, and inoculation on total leaf area (a), total biomass (b), and structural carbon costs to acquire nitrogen (c). Soil nitrogen fertilization is represented on the x-axis in all panels. Colored points and trendlines are as explained in Figure 5.1.

**2341** 5.3.5 *Nitrogen fixation*

**2342** Nodule biomass was stimulated by 30% under elevated CO<sub>2</sub> ( $p<0.001$ ; Table 5.5),  
**2343** a pattern that was modified across the fertilization gradient (CO<sub>2</sub>-by-fertilization  
**2344** interaction:  $p=0.479$ ; Table 5.5), but not between inoculation treatments (CO<sub>2</sub>-  
**2345** by-inoculation interaction:  $p=0.404$ ; Table 5.5). Specifically, the negative effect  
**2346** of increasing fertilization on nodule biomass ( $p<0.001$ ; Table 5.5) was stronger  
**2347** under elevated CO<sub>2</sub> (Tukey:  $p<0.001$ ; Fig. 5.5a). An interaction between fertil-  
**2348** ization and inoculation (fertilization-by-inoculation interaction:  $p<0.001$ ; Table  
**2349** 5.5) indicated a stronger negative effect of increasing fertilization in inoculated  
**2350** pots (Tukey:  $p<0.001$ ; Fig. 5.5a).

**2351** There was no effect of CO<sub>2</sub> on nodule: root biomass ( $p=0.767$ ; Table 5.5),  
**2352** although an interaction between CO<sub>2</sub> and inoculation (CO<sub>2</sub>-by-inoculation in-  
**2353** teraction:  $p<0.001$ ; Table 5.5) indicated that the positive effect of inoculation  
**2354** on nodule: root biomass ( $p<0.001$ ; Table 5.5) was stronger under ambient CO<sub>2</sub>  
**2355** (3129% increase; Tukey:  $p<0.001$ ) than elevated CO<sub>2</sub> (379% increase; Tukey:  
**2356**  $p<0.001$ ; Fig. 5.5b). The null effect of CO<sub>2</sub> on nodule: root biomass was consis-  
**2357** tently observed across the fertilization gradient (CO<sub>2</sub>-by-fertilization interaction:  
**2358**  $p=0.183$ ; Table 5.5; Fig. 5.5b). An interaction between fertilization and inocula-  
**2359** tion (fertilization-by-inoculation interaction:  $p<0.001$ ; Table 5.5) indicated that  
**2360** the negative effect of increasing fertilization on nodule: root biomass ( $p<0.001$ ;  
**2361** Table 5.5) was stronger in inoculated pots (Tukey:  $p<0.001$ ; Fig. 5.5b).

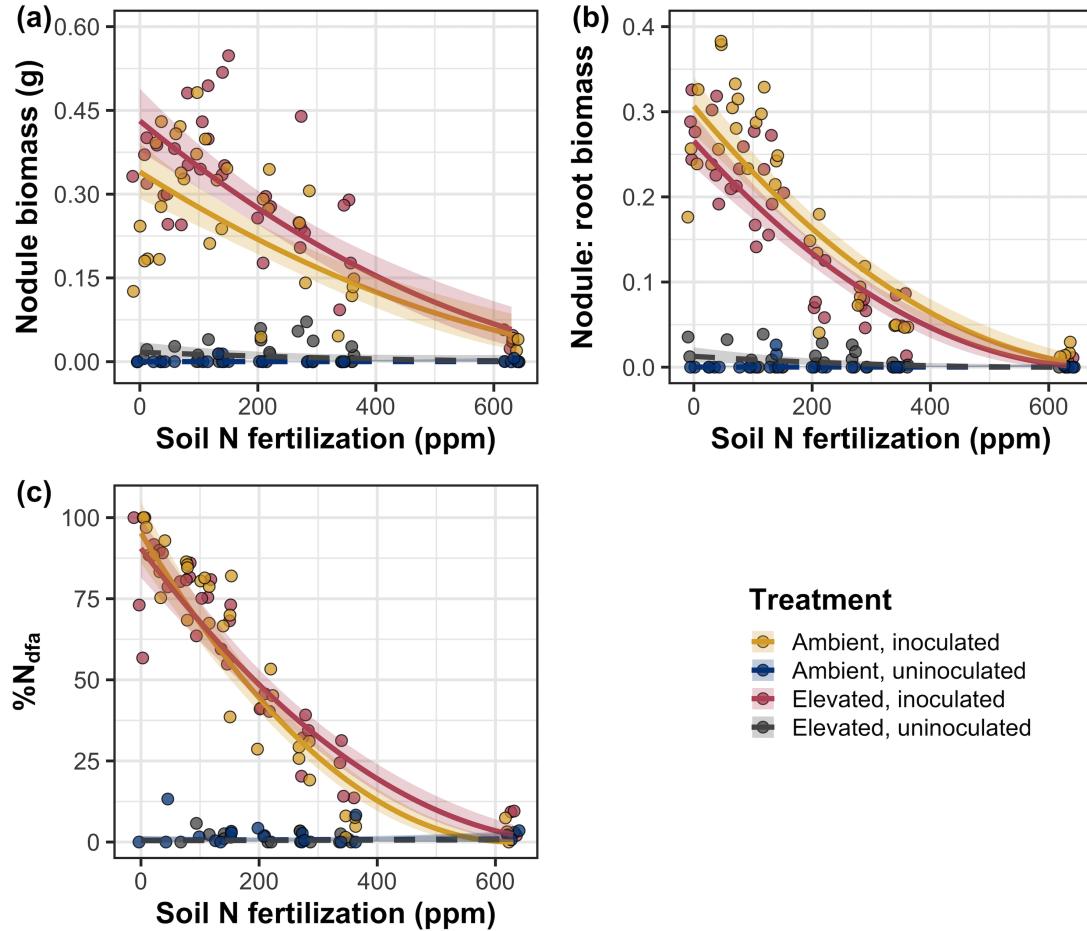

**2362** There was no effect of CO<sub>2</sub> on %N<sub>dfa</sub> ( $p=0.472$ ; Table 5.5), a pattern  
**2363** that was not modified by inoculation (CO<sub>2</sub>-by-inoculation interaction:  $p=0.156$ ;  
**2364** Table 5.5) or fertilization (CO<sub>2</sub>-by-fertilization interaction:  $p=0.099$ ; Table 5.5).

- 2365** An interaction between fertilization and inoculation (fertilization-by-inoculation  
**2366** interaction:  $p<0.001$ ; Table 5.5) indicated that the negative effect of increasing  
**2367** fertilization on  $\%N_{dfa}$  ( $p<0.001$ ; Table 5.5) was only observed in inoculated pots  
**2368** (Tukey:  $p<0.001$ ; Fig. 5.5c).

**Table 5.5.** Effects of CO<sub>2</sub>, fertilization, and inoculation on root nodule biomass (g), plant investments in symbiotic nitrogen fixation (unitless), and percent nitrogen fixed from the atmosphere (%N<sub>dfa</sub>; unitless)\*

2369 \*Significance determined using Type II Wald  $\chi^2$  tests ( $\alpha=0.05$ ). P-values less than 0.05 are in bold, while p-values  
 2370 between 0.05 and 0.1 are italicized. Superscript letters indicate model coefficients fit to square-root (b) transformed  
 2371 data. Key: df=degrees of freedom;  $\chi^2$ =Wald Type II chi-square test statistic.

**Figure 5.5.** Effects of CO<sub>2</sub>, fertilization, and inoculation on nodule biomass (a), nodule biomass: root biomass (b), and percent nitrogen fixed from the atmosphere (c). Soil nitrogen fertilization is represented on the x-axis. Colored points and trendlines are as explained in Figure 5.1. Curvilinear trendlines occur as a result of back-transforming models where response variables received either a natural log or square root transformation prior to fitting.

**2372** 5.4 Discussion

**2373** In this study, I determined leaf and whole plant acclimation responses of 7-week *G.*  
**2374** *max* seedlings grown under two CO<sub>2</sub> concentrations, two inoculation treatments,  
**2375** and nine soil nitrogen fertilization treatments in a full-factorial growth chamber  
**2376** experiment. In support of hypotheses and patterns expected from theory, elevated  
**2377** CO<sub>2</sub> reduced  $N_{\text{area}}$ ,  $V_{\text{cmax25}}$ , and  $J_{\text{max25}}$ . The relatively stronger reduction in  
**2378**  $V_{\text{cmax25}}$  than  $J_{\text{max25}}$  under elevated CO<sub>2</sub> resulted in a stimulation in  $J_{\text{max25}}:V_{\text{cmax25}}$   
**2379** under elevated CO<sub>2</sub>. Reduced  $V_{\text{cmax25}}$  and  $J_{\text{max25}}$  under elevated CO<sub>2</sub> was similar  
**2380** across fertilization and inoculation treatments, indicating that the CO<sub>2</sub> responses  
**2381** were not associated with nitrogen limitation. Interestingly, results indicate that  
**2382** elevated CO<sub>2</sub> increased the fraction of leaf nitrogen allocated to photosynthesis  
**2383** and structure, leading to a stimulation in nitrogen use efficiency under elevated  
**2384** CO<sub>2</sub> despite the apparent reduction in  $N_{\text{area}}$ ,  $V_{\text{cmax25}}$ , and  $J_{\text{max25}}$ .

**2385** Downregulated leaf biochemical process rates under elevated CO<sub>2</sub> corre-  
**2386** sponded with strong increases in total leaf area and total biomass. Increased  
**2387** whole plant growth under elevated CO<sub>2</sub> was generally enhanced with increasing  
**2388** fertilization and were negatively related to structural carbon costs to acquire ni-  
**2389** trogen. Inoculation generally did not modify whole plant responses to elevated  
**2390** CO<sub>2</sub> across the fertilization gradient, likely due to a strong reduction in root nodu-  
**2391** lation with increasing fertilization. However, strong positive effects of inoculation  
**2392** on whole plant growth were observed under low fertilization, consistent with hy-  
**2393** potheses. Overall, observed leaf and whole plant acclimation responses to CO<sub>2</sub>  
**2394** support hypotheses and patterns expected from photosynthetic least-cost theory,  
**2395** showing that leaf acclimation responses to CO<sub>2</sub> were decoupled from soil nitrogen

2396 availability and ability to acquire nitrogen via symbiotic nitrogen fixation. In-  
2397 stead, leaf and whole plant acclimation responses to CO<sub>2</sub> were driven by optimal  
2398 resource investment to photosynthetic capacity, where optimal resource invest-  
2399 ment at the leaf level maximized nitrogen allocation to structures that support  
2400 whole plant growth.

2401 5.4.1 *Soil nitrogen fertilization has divergent effects on leaf and whole plant*  
2402 *acclimation responses to CO<sub>2</sub>*

2403 Elevated CO<sub>2</sub> reduced  $N_{\text{area}}$ ,  $V_{\text{cmax25}}$ ,  $J_{\text{max25}}$ , and stomatal conductance by 29%,  
2404 16%, 10%, and 20%, respectively. The larger reduction in  $V_{\text{cmax25}}$  than  $J_{\text{max25}}$  led  
2405 to an 8% stimulation in  $J_{\text{max25}}:V_{\text{cmax25}}$ , while the larger reduction in  $N_{\text{area}}$  than  
2406  $V_{\text{cmax25}}$  resulted in a 21% stimulation in the fraction of leaf nitrogen allocated to  
2407 photosynthesis under elevated CO<sub>2</sub>. These acclimation responses are directionally  
2408 consistent with previous studies that have investigated or reviewed leaf acclima-  
2409 tion responses to CO<sub>2</sub> (Drake et al. 1997; Makino et al. 1997; Ainsworth et al.  
2410 2002; Ainsworth and Long 2005; Ainsworth and Rogers 2007; Smith and Dukes  
2411 2013; Smith and Keenan 2020; Poorter et al. 2022), and follow patterns expected  
2412 from photosynthetic least-cost theory (Wright et al. 2003; Prentice et al. 2014;  
2413 Smith et al. 2019; Smith and Keenan 2020). Together, increased  $J_{\text{max25}}:V_{\text{cmax25}}$   
2414 and the fraction of leaf nitrogen allocated to photosynthesis under elevated CO<sub>2</sub>  
2415 provide strong support for the idea that leaves reduced  $V_{\text{cmax25}}$  such that net photo-  
2416 synthesis rates approached becoming equally co-limited by Rubisco carboxylation  
2417 and RuBP regeneration (Chen et al. 1993; Maire et al. 2012) while optimizing  
2418 resource use efficiency.

2419 Increasing fertilization and inoculation induced strong positive effects on  
2420  $N_{\text{area}}$ ,  $V_{\text{cmax25}}$ ,  $J_{\text{max25}}$ . The positive effect of increasing fertilization on  $N_{\text{area}}$  was  
2421 enhanced under ambient CO<sub>2</sub>, which, paired with the reduction  $N_{\text{area}}$  under el-  
2422 evated CO<sub>2</sub>, resulted in a stronger reduction in  $N_{\text{area}}$  under elevated CO<sub>2</sub> with  
2423 increasing fertilization and in inoculated pots. These patterns suggest that  $N_{\text{area}}$   
2424 responses to CO<sub>2</sub> were at least partially dependent on soil nitrogen fertilization  
2425 and nitrogen acquisition strategy. However, increased fractions of leaf nitrogen  
2426 allocated to Rubisco, bioenergetics, or photosynthesis under elevated CO<sub>2</sub> were  
2427 not modified across the fertilization gradient and was only marginally enhanced in  
2428 inoculated pots. These patterns suggest that increasing soil nitrogen fertilization  
2429 and inoculation did not change relative nutrient investment in photosynthetic tis-  
2430 sues, supporting the idea that leaf acclimation responses to CO<sub>2</sub> were decoupled  
2431 from soil nitrogen availability.

2432 Leaf acclimation responses to elevated CO<sub>2</sub> corresponded with a 62% and  
2433 100% increase in total leaf area and total biomass, respectively. Increases in to-  
2434 tal leaf area and total biomass under elevated CO<sub>2</sub> corresponded with generally  
2435 larger structural carbon costs to acquire nitrogen, a pattern driven by an increase  
2436 in belowground carbon biomass and reduction in whole plant nitrogen biomass.  
2437 This result suggests that elevated CO<sub>2</sub> reduces plant nitrogen uptake efficiency,  
2438 which does not explain why plants grown under elevated CO<sub>2</sub> generally had higher  
2439 biomass and total leaf area, unless growth stimulations under elevated CO<sub>2</sub> were  
2440 driven by reductions in per-tissue nitrogen demand (Dong et al. 2022). Interest-  
2441 ingly, strong negative effects of increasing fertilization on structural carbon costs  
2442 to acquire nitrogen, which were generally similar between CO<sub>2</sub> concentrations,

**2443** were driven by stronger increases in whole plant nitrogen biomass than below-  
**2444** ground carbon biomass. This response allowed plants to increase nitrogen uptake  
**2445** efficiency with increasing fertilization, providing a possible mechanism that ex-  
**2446** plains why increasing fertilization increased the positive effect of elevated CO<sub>2</sub> on  
**2447** whole plant growth.

**2448** Interestingly, results indicate that increased total leaf area and whole plant  
**2449** growth under elevated CO<sub>2</sub> was not modified by inoculation despite an apparent  
**2450** general negative effect of inoculation on  $N_{cost}$ . This response could have been  
**2451** due to the strong negative effect of increasing fertilization on nodulation, which  
**2452** may have masked any effect of inoculation treatments in high fertilization treat-  
**2453** ments. Reductions in nodulation with increasing fertilization are commonly ob-  
**2454** served patterns that allow species optimize nitrogen uptake efficiency as costs to  
**2455** acquire nitrogen via direct uptake become more similar (Gibson and Harper 1985;  
**2456** Rastetter et al. 2001). In this study, pairwise comparisons indicated strong pos-  
**2457** itive effects of inoculation on total leaf area and total biomass (158% increase in  
**2458** total leaf area, 119% increase in total biomass) under elevated CO<sub>2</sub> at 0 ppm N  
**2459** ( $p<0.05$  in both cases), but no observable inoculation effect on total leaf area or  
**2460** total biomass under elevated CO<sub>2</sub> at 350 ppm N or 630 ppm N ( $p>0.05$  in both  
**2461** cases). While these responses did not generally differ from those observed under  
**2462** ambient CO<sub>2</sub>, they do confirm the hypothesis that positive effects of inoculation  
**2463** on whole plant growth responses to elevated CO<sub>2</sub> would decrease with increasing  
**2464** fertilization. These results also support the paradigm that symbiotic nitrogen  
**2465** fixation is a nutrient acquisition strategy that may allow plants who sustain such  
**2466** symbioses to have competitive advantages for resources than species not capable

**2467** of forming such symbioses.

**2468** Combined, results reported here suggest that soil nitrogen availability plays  
**2469** divergent roles in shaping leaf and whole plant acclimation responses to CO<sub>2</sub>. Leaf  
**2470** acclimation responses were generally decoupled from fertilization, while whole  
**2471** plant acclimation responses relied heavily on an increase in nitrogen uptake ef-  
**2472** ficiency and consequent reduction in costs of acquiring nitrogen associated with  
**2473** increasing fertilization. Whole plant responses to CO<sub>2</sub> indicated that fertilization  
**2474** may play a more important role in determining whole plant acclimation responses  
**2475** to CO<sub>2</sub> than nitrogen acquisition strategy, although any inoculation effect was  
**2476** likely masked by the strong reduction in root nodulation with increasing fertil-  
**2477** ization. These results suggest that plants acclimate to CO<sub>2</sub> in nitrogen-limited  
**2478** systems by minimizing the number of optimally coordinated leaves, and that re-  
**2479** ductions in leaf nitrogen content under elevated CO<sub>2</sub> are not driven by changes  
**2480** in soil nitrogen availability as has been previously implied.

**2481** 5.4.2 *Implications for future model development*

**2482** Many terrestrial biosphere models predict photosynthetic capacity through plant  
**2483** functional group-specific linear regressions between  $N_{\text{area}}$  and  $V_{\text{cmax}}$  (Rogers 2014;  
**2484** Rogers et al. 2017), which assumes that leaf nitrogen-photosynthesis relation-  
**2485** ships are constant across growing environments. These results build on previ-  
**2486** ous work suggesting that leaf nitrogen-photosynthesis relationships dynamically  
**2487** change across growing environments (Luo et al. 2021; Dong et al. 2022), showing  
**2488** that CO<sub>2</sub> concentration increases the fraction of leaf nitrogen content allocated to  
**2489** photosynthesis independent of fertilization or acquisition strategy. Additionally,  
**2490** increasing fertilization strongly decreased the fraction of leaf nitrogen allocated

2491 to photosynthesis, a response that was largely determined by acquisition strategy.  
2492 Specifically, reductions in the fraction of leaf nitrogen allocated to photosynthesis  
2493 with increasing fertilization were only observed in inoculated pots that had less  
2494 finite access to nitrogen, suggesting that constant leaf nitrogen-photosynthesis  
2495 relationships may only be apparent in environments where nitrogen is limiting.  
2496 Terrestrial biosphere models that parameterize photosynthetic capacity through  
2497 linear relationships between  $N_{\text{area}}$  and  $V_{\text{cmax}}$  (Rogers 2014; Rogers et al. 2017) may  
2498 therefore be overestimating photosynthetic capacity in systems where nitrogen is  
2499 not as limiting. Such models are also not capable of detecting stimulations in the  
2500 fraction of leaf nitrogen allocated to photosynthesis with increasing  $\text{CO}_2$  concen-  
2501 tration. The inability of models to predict these responses likely contributes to the  
2502 widespread divergence of model simulations under future environmental scenarios  
2503 (Friedlingstein et al. 2014; Davies-Barnard et al. 2020), and should therefore be  
2504 a target for resolving in future generations of terrestrial biosphere models.

2505 These results demonstrate that optimal resource investment to photosyn-  
2506 thetic capacity defines leaf acclimation responses to elevated  $\text{CO}_2$ , and that these  
2507 responses were independent of fertilization or inoculation treatment. Current  
2508 model approaches for simulating photosynthetic responses to  $\text{CO}_2$  generally in-  
2509 voke patterns expected from progressive nitrogen limitation, where reductions  
2510 in  $N_{\text{area}}$ , and therefore photosynthetic capacity, due to elevated  $\text{CO}_2$  are formu-  
2511 lated as a function of progressive reductions in soil nitrogen availability. Results  
2512 reported here contradict this formulation, suggesting that the leaf acclimation re-  
2513 sponse is driven by optimal resource investment to photosynthetic capacity and  
2514 is independent of soil resource supply. Optimality models that leverage prin-

2515 ciples from optimal coordination and photosynthetic least-cost theories (Wang  
2516 et al. 2017; Stocker et al. 2020; Scott and Smith 2022) are capable of capturing  
2517 such acclimation responses to CO<sub>2</sub> (Smith and Keenan 2020), suggesting that the  
2518 implementation of these models may improve the simulation of photosynthetic  
2519 processes in terrestrial biosphere models under increasing CO<sub>2</sub> concentrations.

2520 5.4.3 *Study limitations and future directions*

2521 There are two study limitations that must be addressed to contextualize patterns  
2522 observed in this study. First, restricting the volume of belowground substrate  
2523 via a potted experiment does not adequately replicate belowground environments  
2524 of natural systems, and therefore may modify effects of soil resource availability  
2525 and inoculation on plant nitrogen uptake. This limitation may be particularly  
2526 relevant if pot size limits whole plant growth (Poorter et al. 2012). I attempted  
2527 to minimize the extent of pot size limitation experienced in the first experimen-  
2528 tal chapter while accounting for the expected stimulation in whole plant growth  
2529 under elevated CO<sub>2</sub> by using 6-liter pots. Despite attempts to minimize growth  
2530 limitation imposed by pot volume, fertilization and CO<sub>2</sub> treatments increased the  
2531 biomass: pot volume ratio such that all treatment combinations to exceed 1 g L<sup>-1</sup>  
2532 biomass: pot volume under high fertilization (Table D3; Fig. D2). The 1 g L<sup>-1</sup>  
2533 biomass: pot volume recommendation from Poorter et al. (2012) was designated  
2534 to avoid growth limitation imposed by pot volume. However, if pot size limita-  
2535 tion indeed limited whole plant growth, then structural carbon costs to acquire  
2536 nitrogen, belowground carbon biomass, whole plant nitrogen biomass, and whole  
2537 plant biomass should each exhibit strong saturation points with increasing fertil-

2538 ization, which was not observed here. Importantly, leaf acclimation responses to  
2539 CO<sub>2</sub> observed in this study are consistent with findings reported in (Smith and  
2540 Keenan 2020), who used data from field manipulation experiments that did not  
2541 have any belowground space limitation.

2542 Second, this study evaluated leaf and whole plant responses to CO<sub>2</sub> in 7-  
2543 week seedlings. Given the long-term scale of the progressive nitrogen limitation  
2544 hypothesis, patterns observed here should be validated in longer-term nitrogen  
2545 manipulation experiments. Previous work in free air CO<sub>2</sub> enrichment experiments  
2546 show some support for patterns expected from the progressive nitrogen limitation  
2547 hypothesis (Reich et al. 2006; Norby et al. 2010), although results are not consis-  
2548 tent across experimental sites (Finzi et al. 2006; Moore et al. 2006; Liang et al.  
2549 2016). I found some support for patterns expected by the progressive nitrogen  
2550 limitation hypothesis, namely the increase in plant nitrogen uptake under elevated  
2551 CO<sub>2</sub> (Luo et al. 2004), though leaf acclimation responses to CO<sub>2</sub> were strongly  
2552 indicative of optimal resource investment to photosynthetic capacity as expected  
2553 from photosynthetic least-cost theory (Prentice et al. 2014; Smith et al. 2019;  
2554 Smith and Keenan 2020).

2555 5.4.4 *Conclusions*

2556 This study provides strong evidence suggesting that leaf acclimation responses  
2557 to elevated CO<sub>2</sub> did not vary with soil nitrogen fertilization or ability to acquire  
2558 nitrogen through symbiotic nitrogen fixation. However, whole plant acclimation  
2559 responses to CO<sub>2</sub> were dependent on fertilization, where increasing fertilization  
2560 increased the positive effect of whole plant growth under elevated CO<sub>2</sub>. Results  
2561 also indicate that fertilization played a relatively more important role in modify-

2562 ing whole plant responses to CO<sub>2</sub> than inoculation with symbiotic nitrogen-fixing  
2563 bacteria, perhaps due to a reduction in nodulation across the fertilization gra-  
2564 dient. These patterns strongly support the hypothesis that leaf and whole plant  
2565 acclimation responses are driven by optimal resource investment to photosynthetic  
2566 capacity, and that leaf acclimation responses to CO<sub>2</sub> were not modified by changes  
2567 in soil nitrogen availability. These results build on previous work suggesting that  
2568 constant leaf nitrogen-photosynthesis relationships are dynamic and change across  
2569 growing environments, calling the current formulation of photosynthetic processes  
2570 used in many terrestrial biosphere models into question.

2571

## Chapter 6

2572

### Conclusions

2573 The experiments included in this dissertation test mechanisms that drive patterns  
2574 expected from photosynthetic least-cost theory across various edaphic and climatic  
2575 gradients. Specifically, I investigate environmental drivers of carbon costs to ac-  
2576 quire nitrogen, tradeoffs between nitrogen and water use, and plant acclimation  
2577 responses to CO<sub>2</sub>. These experiments provide important empirical data needed to  
2578 test assumptions made in optimality models that leverage photosynthetic least-  
2579 cost frameworks, and are among the first manipulative experiments to show sup-  
2580 port for patterns expected from theory. Below, I summarize main findings of each  
2581 chapter, synthesize common patterns observed across experiments, and conclude  
2582 with a few study ideas that I think will help refine our understanding of plant  
2583 nutrient acquisition and allocation responses to environmental change leveraging  
2584 patterns predicted by photosynthetic least-cost theory.

2585 In the first experimental chapter, I quantified carbon costs to acquire ni-  
2586 trogen in a species capable of forming associations with symbiotic nitrogen-fixing  
2587 bacteria (*Glycine max*) and a species not capable of forming such associations  
2588 (*Gossypium hirsutum*) grown under four soil nitrogen fertilization treatments and  
2589 four light availability treatments in a full factorial greenhouse experiment. Sup-  
2590 porting hypotheses, increasing light availability increased carbon costs to acquire  
2591 nitrogen in both species due to a larger increase in belowground carbon biomass  
2592 than whole plant nitrogen biomass. In further support of hypotheses, increasing  
2593 fertilization decreased carbon costs to acquire nitrogen due to a larger increase in

2594 whole plant nitrogen biomass than belowground carbon biomass. Root nodulation  
2595 data indicated that *G. max* shifted relative carbon allocation from nitrogen fixa-  
2596 tion to direct uptake with increasing fertilization, which may explain the reduced  
2597 responsiveness of *G. max* carbon costs to acquire nitrogen across the fertilization  
2598 gradient.

2599 Despite evidence that reductions in the response of *G. max* carbon costs  
2600 to acquire nitrogen to increasing fertilization may have been driven by shifts away  
2601 from nitrogen fixation with increasing fertilization, I urge caution in assigning  
2602 causality to the differential response of carbon costs to acquire nitrogen between  
2603 species. This is because *G. max* and *G. hirsutum* are not phylogenetically related  
2604 and have different life histories. Differences in life history between the two species  
2605 limit my ability to assess whether reductions in the negative effect of increasing  
2606 fertilization on carbon costs to acquire nitrogen in *G. max* were driven by shifts  
2607 to direct uptake with increasing fertilization. However, these patterns were later  
2608 confirmed in the fourth experimental chapter, where similar weaker negative ef-  
2609 fects of increasing fertilization on carbon costs to acquire nitrogen were observed  
2610 in *G. max* that were inoculated with symbiotic nitrogen-fixing bacteria compared  
2611 to *G. max* that were left uninoculated across a similar soil nitrogen fertilization  
2612 gradient.

2613 In the second experimental chapter, I assessed whether changes in soil  
2614 nitrogen availability or soil pH drove changes in nitrogen-water use tradeoffs pre-  
2615 dicted by photosynthetic least-cost theory. I measured leaf traits of mature upper  
2616 canopy deciduous trees growing in a nine-year nitrogen-by-sulfur field manipula-  
2617 tion experiment, where experimental sulfur additions were added with intent to

2618 acidify plots. Following patterns expected from the theory, increasing soil nitrogen  
2619 availability was associated with increased leaf nitrogen content, but not net photo-  
2620 synthesis, resulting in an increase in photosynthetic nitrogen use efficiency. In  
2621 further support of theory, increasing soil nitrogen availability exhibited slight, but  
2622 nonsignificant, decreases in leaf  $C_i:C_a$  and increases in measures of photosynthetic  
2623 capacity. Perhaps the strongest evidence for the theory was a strong negative  
2624 relationship between leaf nitrogen content and leaf  $C_i:C_a$ , of which increased with  
2625 increasing soil nitrogen availability through a stronger increase in leaf nitrogen  
2626 content than leaf  $C_i:C_a$ .

2627 I found no effect of soil pH on nitrogen-water use tradeoffs aside from a  
2628 marginal reduction in net photosynthesis rates that marginally reduced photosyn-  
2629 thetic nitrogen use efficiency with increasing soil pH. Directionally, reductions in  
2630 photosynthetic nitrogen use efficiency with increasing soil pH were expected per  
2631 theory; however, this response was driven by no change in leaf nitrogen content  
2632 and a reduction in net photosynthesis. Theory predicts that these tradeoffs should  
2633 be driven by no change in net photosynthesis and an increase in leaf nitrogen con-  
2634 tent. The general null leaf response to changing soil pH may have been due to  
2635 experimental treatments directly increased soil nitrogen availability and affected  
2636 soil pH in opposite patterns, suggesting that soil nitrogen availability may be more  
2637 important in dictating nitrogen-water use tradeoffs than soil pH per se.

2638 In the third experimental chapter, I quantified variance in leaf nitrogen  
2639 content across a precipitation and soil resource availability gradient in Texan  
2640 grasslands. Specifically, I measured area-based leaf nitrogen content, components  
2641 of area-based leaf nitrogen content (leaf mass per unit leaf area, leaf nitrogen per

**2642** unit dry biomass), leaf  $C_i:C_a$ , and the unit cost of acquiring nitrogen relative to  
**2643** water in 520 individuals comprising 57 species. I found that variance in area-  
**2644** based leaf nitrogen content was positively associated with increasing soil nitrogen  
**2645** availability, soil moisture, vapor pressure deficit, and was negatively related to  
**2646** increasing leaf  $C_i:C_a$ . Following patterns expected from theory, a path analysis  
**2647** revealed that the positive soil nitrogen-leaf nitrogen relationship was driven by a  
**2648** positive relationship between soil nitrogen availability and the unit cost of acquir-  
**2649** ing and using nitrogen relative to water, a positive relationship between the unit  
**2650** cost of acquiring and using nitrogen relative to water, and negative relationship  
**2651** between leaf  $C_i:C_a$  and leaf mass per unit leaf area. Interestingly, there was no  
**2652** effect of  $C_i:C_a$  on leaf nitrogen content per unit dry biomass, indicating that vari-  
**2653** ance in area-based leaf nitrogen content across the environmental gradient was  
**2654** driven by a change in leaf morphology and not leaf chemistry.

**2655** In the fourth experimental chapter, I quantified leaf and whole plant accli-  
**2656** mation responses in *G. max* grown under two atmospheric CO<sub>2</sub> levels, with and  
**2657** without inoculation with *Bradyrhizobium japonicum*, and across nine nitrogen fer-  
**2658** tilization treatments in a full factorial growth chamber experiment. I found strong  
**2659** evidence that leaf nitrogen content,  $V_{cmax}$ , and  $J_{max}$  were each downregulated un-  
**2660** der elevated CO<sub>2</sub>. A stronger downregulation in  $V_{cmax}$  than  $J_{max}$  and stronger  
**2661** downregulation in leaf nitrogen content than  $V_{cmax}$  or  $J_{max}$  provided strong sup-  
**2662** port suggesting that leaves were acclimating to elevated CO<sub>2</sub> by optimizing leaf  
**2663** photosynthetic resource use efficiency to achieve optimal coordination. In striking  
**2664** support of my hypotheses, I find strong evidence suggesting that leaf acclimation  
**2665** responses to elevated CO<sub>2</sub> were decoupled from soil nitrogen fertilization and in-

**2666** oculation treatment, despite apparent strong increases in leaf nitrogen content,  
**2667**  $V_{\text{cmax}}$ , and  $J_{\text{max}}$  with increasing fertilization and in inoculated pots. These find-  
**2668** ings contrast the current formulation of photosynthetic processes in terrestrial  
**2669** biosphere models, where many models simulate downregulations in leaf nitrogen  
**2670** content under elevated CO<sub>2</sub> as a function of progressive nitrogen limitation.

**2671** There are currently two iterations of optimality models that employ the  
**2672** use of patterns expected from photosynthetic least-cost theory, one for C<sub>3</sub> species  
**2673** (Wang et al. 2017; Smith et al. 2019; Stocker et al. 2020) and one more recently  
**2674** developed for C<sub>4</sub> species (Scott and Smith 2022). In both model variants, costs  
**2675** to acquire and use nitrogen relative to water are held constant using a global  
**2676** dataset of δ<sup>13</sup>C (Cornwell et al. 2018). Throughout experiments, I show strong  
**2677** evidence suggesting that costs to acquire and use nitrogen are dynamic and vary  
**2678** predictably across environmental gradients, and that changes in these costs scale  
**2679** to alter leaf nitrogen-water use tradeoffs and acclimation responses to changing  
**2680** environments in ways predicted through photosynthetic least-cost theory. Thus,  
**2681** while optimality model simulations show good agreement with measured data  
**2682** (Smith et al. 2019; Stocker et al. 2020), such models may not be capturing an  
**2683** important source of variability in leaf nitrogen-water use tradeoffs by holding costs  
**2684** of resource use constant across environmental gradients.

**2685** First principles of photosynthetic least-cost theory suggest that, in a given  
**2686** environment, plants optimize photosynthesis rates by sacrificing inefficient use of  
**2687** a relatively more abundant (and less costly to acquire) resource for more efficient  
**2688** use of a relatively less abundant (and more costly to acquire) resource. Through-  
**2689** out experimental chapters, I show strong support for these patterns across ex-

2690 periments, where increasing soil nitrogen fertilization generally decreased the cost  
2691 of acquiring nitrogen relative to water, a pattern that scaled to influence leaf  
2692 nitrogen-water use tradeoffs. I did not find evidence to suggest that soil moisture  
2693 influenced nitrogen-water use tradeoffs, though this was due to strong covariation  
2694 between soil moisture and soil nitrogen availability. Overall, findings across exper-  
2695 iments provide empirical validation of photosynthetic least-cost theory needed to  
2696 further develop optimality models and eventually implement such models in ter-  
2697 restrial biosphere model products. Many terrestrial biosphere model products do  
2698 not include robust frameworks for simulating acclimation responses to changing  
2699 environmental conditions, and empirical findings shown here provide some support  
2700 that optimality models that leverage photosynthetic least-cost theory predictions  
2701 may improve the ability of terrestrial biosphere models to accurately simulate  
2702 photosynthetic processes.

2703       Many terrestrial biosphere models predict photosynthetic capacity through  
2704 plant functional group-specific linear regressions between area-based leaf nitrogen  
2705 content and  $V_{cmax}$  (Rogers 2014; Rogers et al. 2017), which assumes that leaf  
2706 nitrogen-photosynthesis relationships are constant across growing environments.  
2707 I found constant leaf nitrogen-photosynthesis relationships with increasing soil ni-  
2708 trogen availability in the nitrogen-by-sulfur field manipulation experiment. How-  
2709 ever, results from the CO<sub>2</sub>-by-nitrogen-by-inoculation manipulation experiment  
2710 indicated that leaf nitrogen-photosynthesis responses to soil nitrogen availability  
2711 were dependent on whether nitrogen was limiting. Further investigation regard-  
2712 ing the effect of soil nitrogen availability in modifying leaf nitrogen-photosynthesis  
2713 relationships is warranted to better understand the generality of leaf nitrogen pho-

**2714** tosynthesis relationships across environmental gradients. However, findings from  
**2715** these experiments suggest that representing photosynthetic processes through pos-  
**2716** itive relationships between soil nitrogen availability, leaf nitrogen, and photosyn-  
**2717** thetic capacity are likely contributing to erroneous errors in model simulations and  
**2718** may explain the high degree of divergence in simulated processes across terrestrial  
**2719** biosphere models (Friedlingstein et al. 2014; Davies-Barnard et al. 2020).

**2720** The experiments included in this dissertation have provided a strong foun-  
**2721** dation for me to continue growing as a plant physiological ecologist. I envision  
**2722** five primary avenues for future research that build on the work presented here,  
**2723** which are briefly summarized below:

**2724** 1. Manipulative and environmental gradient experiments included here were  
**2725** designed to provide empirical data needed to test photosynthetic least-cost  
**2726** theory assumptions. While these results show promising patterns for pat-  
**2727** terns expected from photosynthetic least-cost theory, they do not necessarily  
**2728** address whether these patterns follow those simulated by optimality models  
**2729** that leverage photosynthetic least-cost principles. Thus, a clear future di-  
**2730** rection of these experiments would be to conduct model-data comparisons  
**2731** using data collected here (or similar experiments) to compare against opti-  
**2732** mality model simulations.

**2733** 2. Experiments included here explicitly quantify effects of symbiotic nitrogen  
**2734** fixation on carbon costs to acquire nitrogen, nitrogen-water use tradeoffs,  
**2735** and leaf nitrogen-photosynthesis relationships. However, carbon costs to ac-  
**2736** quire nitrogen also vary in species that associate with different mycorrhizal  
**2737** types (Brzostek et al. 2014; Terrer et al. 2018), and dominant mycorrhizal

2738 type in an ecosystem has been shown to determine net biogeochemical cycle  
2739 dynamics in deciduous forests of the northeastern United States (Phillips  
2740 et al. 2013). Thus, future work should consider conducting similar experi-  
2741 ments while manipulating mycorrhizal association to better understand how  
2742 microbial symbioses modify leaf and whole plant acclimation responses to  
2743 changing environments.

2744 3. Recent work indicates a high degree of variance in symbiotic nitrogen fixa-  
2745 tion rates across terrestrial biosphere models (Meyerholt et al. 2016; Davies-  
2746 Barnard et al. 2020), perhaps due to nitrogen fixation rates that are im-  
2747 plemented across terrestrial biosphere models as a function of temperature  
2748 (Houlton et al. 2008). While energetic costs of nitrogen fixation are de-  
2749 pendent on temperature, I show that structural carbon costs to acquire  
2750 nitrogen via symbiotic nitrogen fixation are driven by factors that influence  
2751 demand to acquire nitrogen (i.e. CO<sub>2</sub>, light) and are modified by soil ni-  
2752 tragen supply. The light-by-nitrogen greenhouse experiment was published  
2753 in *Journal of Experimental Botany*, and a reviewer encouraged future work  
2754 to include a model-data comparison comparing structural carbon costs to  
2755 acquire nitrogen measured in the experiment to carbon costs to acquire ni-  
2756 tragen simulated by the FUN biogeochemical model (Fisher et al. 2010;  
2757 Brzostek et al. 2014; Allen et al. 2020). Conveniently, FUN calculates car-  
2758 bon costs to acquire nitrogen following the same calculation used in the first  
2759 and fourth experimental chapter. Conducting such a model-data comparison  
2760 would be a useful step toward identifying biases in the FUN biogeochemi-  
2761 cal model, which is currently coupled to several terrestrial biosphere models

- 2762 (Clark et al. 2011; Shi et al. 2016; Lawrence et al. 2019; Davies-Barnard  
2763 et al. 2020).
- 2764 4. Carbon costs to acquire nitrogen relative to water were quantified at the  
2765 leaf level as a function of  $\delta^{13}\text{C}$  and vapor pressure deficit, while structural  
2766 carbon costs to acquire nitrogen were quantified at the whole plant level  
2767 as the ratio of belowground carbon allocation per unit whole plant nitro-  
2768 gen biomass. As increasing soil nitrogen availability decreases both leaf and  
2769 whole plant estimates of costs to acquire and use nitrogen, one might expect  
2770 leaf and whole plant carbon cost to acquire nitrogen estimates to covary. Fu-  
2771 ture work should consider investigating if leaf and whole plant estimates of  
2772 carbon costs to acquire nitrogen covary and evaluate whether environmental  
2773 conditions (or species acquisition strategy) modifies any of this possible co-  
2774 variance. Strong covariance between leaf and whole plant costs of nitrogen  
2775 acquisition could be a possible avenue to implement frameworks for allowing  
2776 costs of nitrogen acquisition to vary in optimality models, as the FUN model  
2777 calculates carbon costs of nitrogen acquisition at the whole plant level.
- 2778 5. While experiments included here target effects of soil nitrogen availability  
2779 on carbon costs to acquire nitrogen and associated leaf nitrogen-water use  
2780 tradeoffs, photosynthetic least-cost theory predicts that plants acclimate  
2781 their photosynthetic processes by minimizing the summed cost of nutrient  
2782 (not just nitrogen) and water use. Therefore, the theory would predict  
2783 similar leaf acclimation responses across soil phosphorus or other nutrient  
2784 availability gradients. Recent iterations of the FUN biogeochemical cycle  
2785 includes a framework for determining the carbon and nitrogen cost of ac-

**2786** quiring and using phosphorus, which similarly varies in species with different  
**2787** nutrient acquisition strategies (Allen et al. 2020). The implementation of  
**2788** this model in a terrestrial biosphere model (E3SM) was also recently shown  
**2789** to improve model performance of ecosystem nutrient limitation (Braghieri  
**2790** et al. 2022). As nitrogen and phosphorus commonly co-limit leaf photo-  
**2791** synthesis and primary productivity, extending experiments reported here to  
**2792** investigate carbon and nitrogen costs of phosphorus use, and whether these  
**2793** patterns scale to leaf nutrient-water use tradeoffs would be a useful next  
**2794** step in understanding extensions and limitations of photosynthetic least-  
**2795** cost theory.

**2796** The experiments included in this dissertation and the proposed experiments sum-  
**2797** marized above provide a snapshot view of the things that I have learned through-  
**2798** out my time as a graduate student. I am excited to continue learning and growing  
**2799** as a plant ecophysiologicalist, ecologist, and scientist, and look forward to continuing  
**2800** along my journey of investigating nutrient acquisition and allocation responses to  
**2801** global change.

**3663      acquire nitrogen are determined by nitrogen and light availability in**  
**3664      two species with different nitrogen acquisition strategies"**

**Table A1.** Summary table containing volumes of compounds used to create modified Hoagland's solutions for each soil nitrogen fertilization treatment. All volumes are expressed as milliliters per liter ( $\text{mL L}^{-1}$ )

Compound	0 ppm N	70 ppm N	210 ppm N	630 ppm N
1 M $\text{NH}_4\text{H}_2\text{PO}_4$	0	0.33	1	1
2 M $\text{KNO}_3$	0	0.67	2	2
2 M $\text{Ca}(\text{NO}_3)_2$	0	0.67	2	2
1 M $\text{NH}_4\text{NO}_3$	0	0.33	1	0
8 M $\text{NH}_4\text{NO}_3$	0	0	0	2
1 M $\text{KH}_2\text{PO}_4$	1	0.67	0	0
1 M KCl	4	1.33	0	0
1 M $\text{CaCO}_3$	4	3	0	0
2 M $\text{MgSO}_4$	1	1	1	1
10% Fe-EDTA	1	1	1	1
Trace Elements	1	1	1	1

**Table A2.** Analysis of variance results exploring species-specific effects of light availability, nitrogen fertilization, and their interactions on the ratio of whole plant biomass to pot volume (g L<sup>-1</sup>)\*

	df	Coefficient	$\chi^2$	p
<i>G. hirsutum</i>				
Intercept		0.740	-	-
Light (L)	1	-4.23E-03	189.581	<b>&lt;0.001</b>
Nitrogen (N)	1	7.86E-04	17.927	<b>&lt;0.001</b>
L*N	1	-6.61E-06	4.709	<b>0.030</b>
<i>G. max</i>				
Intercept		-0.233	-	-
Light (L)	1	-1.12E-02	69.500	<b>&lt;0.001</b>
Nitrogen (N)	1	8.29E-04	40.297	<b>&lt;0.001</b>
L*N	1	-8.51E-06	5.548	<b>0.019</b>

**3665** \*Significance determined using Wald's  $\chi^2$  tests ( $p=0.05$ ). *P*-values less than 0.05  
**3666** are in bold and *p*-values between 0.05 and 0.1 are italicized. Negative coefficients  
**3667** for light treatments indicate a positive effect of increasing light availability on  
**3668** all response variables, as light availability is treated as percent shade cover in all  
**3669** linear mixed-effects models.

**Table A3.** Slopes of the regression line describing the relationship between each dependent variable and nitrogen fertilization at each light level\*

	Shade cover	Slope
<i>G. hirsutum</i>		
0%		<b>8.29E-04<sup>a</sup></b>
30%		<b>5.74E-04<sup>a</sup></b>
50%		<b>4.03E-04<sup>a</sup></b>
80%		1.48E-04 <sup>a</sup>
<i>G. max</i>		
0%		<b>7.86E-04</b>
30%		<b>5.87E-04</b>
50%		<b>4.55E-04</b>
80%		<i>2.57E-05</i>

**3670** \*Slopes represent estimated marginal mean slopes from linear mixed-effects models described in the Methods. Slopes  
**3671** were calculated using the ‘emmeans’ R package (Lenth 2019). Superscripts indicate slopes fit to natural-log (<sup>a</sup>) or  
**3672** square root (<sup>b</sup>) transformed data. Slopes statistically different from zero (Tukey:  $p < 0.05$ ) are indicated in bold.  
**3673** Marginally significant slopes (Tukey:  $0.05 < p < 0.1$ ) are italicized.

**Figure A1.** Effects of shade cover and nitrogen fertilization on the ratio of plant biomass to rooting volume in *G. hirsutum* (left panel) and *G. max* (right panel). The red horizontal line indicates the recommended  $1 \text{ g L}^{-1}$  threshold for biomass:pot volume recommended by Poorter et al. (2012) to avoid pot size-induced growth limitation. Nitrogen fertilization treatments are represented on the x-axis. Shade cover treatments are represented through colored points and trendlines. Points are jittered for visibility. Yellow points and trendlines represent the 0% shade cover treatment, blue points and trendlines represent the 30% shade cover treatment, green points and trendlines represent the 50% shade cover treatment, and purple points and trendlines represent the 80% shade cover treatment. Solid trendlines indicate slopes that are significantly different from zero (Tukey:  $p < 0.05$ ), while dashed trendlines indicate slopes that are not statistically different from zero.

**Figure B1.** Effects of leaf temperature on net photosynthesis rate (A) and stomatal conductance (B) values when measured at  $400 \mu\text{mol mol}^{-1} \text{CO}_2$ . Leaf temperature is represented on the x-axis, while species are represented as colored points. Colored points and shapes are as explained in Figure 3.1. The dashed blue trendline describes the linear relationship between leaf temperature and each response variable, while the dashed black trendline describes the same relationship with a log-polynomial regression equation.

**3688 Appendix C: Supplemental material for "The relative cost of resource  
3689 use for photosynthesis drives variance in leaf nitrogen content across a  
3690 climate and soil resource availability gradient"**

**3691** C.1 Calculations for soil water holding capacity

**3692** Water holding capacity ( $\theta_{WHC}$ ; mm) was calculated as a function of the volumetric  
**3693** soil water storage at field capacity ( $W_{FC}$ ; m<sup>3</sup> m<sup>-3</sup>), and the volumetric soil water  
**3694** storage at wilting point ( $W_{PWP}$ ; m<sup>3</sup> m<sup>-3</sup>):

$$\theta_{WHC} = (W_{FC} - W_{PWP})(1 - f_{gravel}) * \min(z_{bedrock}, z_{max}) \quad (\text{C4.1})$$

**3695** where  $f_{gravel}$  (%) is the fraction of gravel content in soil,  $z_{bedrock}$  (mm) is the  
**3696** distance to bedrock, and  $z_{max}$  (mm) is the maximum allowable distance to bedrock,  
**3697** set to 2000mm.  $W_{FC}$  is calculated as:

$$\theta_{FC} = k_{fc} + (1.283 * (k_{fc})^2 - 0.374 * k_{fc} - 0.015) \quad (\text{C4.2})$$

**3698** where

$$\begin{aligned} k_{fc} = & -0.251 * f_{sand} + 0.195 * f_{clay} + 0.011 * f_{OM} \\ & + 0.006 * (f_{sand} * f_{OM}) - 0.027 * (f_{clay} \\ & * f_{OM}) + 0.452 * (f_{sand} * f_{clay}) + 0.299 \end{aligned} \quad (\text{C4.3})$$

**3699**  $W_{PWP}$  is calculated as:

$$W_{PWP} = k_{pwp} + (0.14 * k_{pwp} - 0.02) \quad (\text{C4.4})$$

**3700** where

$$\begin{aligned} k_{pwp} = & -0.024 * f_{sand} + 0.487 * f_{clay} + 0.006 * f_{OM} \\ & + 0.005 * (f_{sand} * f_{OM}) - 0.013 * (f_{clay} \\ & * f_{OM}) + 0.068 * (f_{sand} * f_{clay}) + 0.031 \end{aligned} \quad (\text{C4.5})$$

- 3701** In Equations C4.4 and C4.5,  $f_{sand}$  (%) is the fraction of sand content in soil  
**3702** (%),  $f_{clay}$  (%) is the fraction of clay content in soil (%), and  $f_{OM}$  is the fraction of  
**3703** organic matter in soil (%). Organic matter in the soil was calculated by converting  
**3704** soil organic carbon data extracted from SoilGrids 2.0 to soil organic matter using  
**3705** the van Bemmelen factor (1.724 conversion factor).

**Table C1.** List of sampled species and their plant functional group assignment

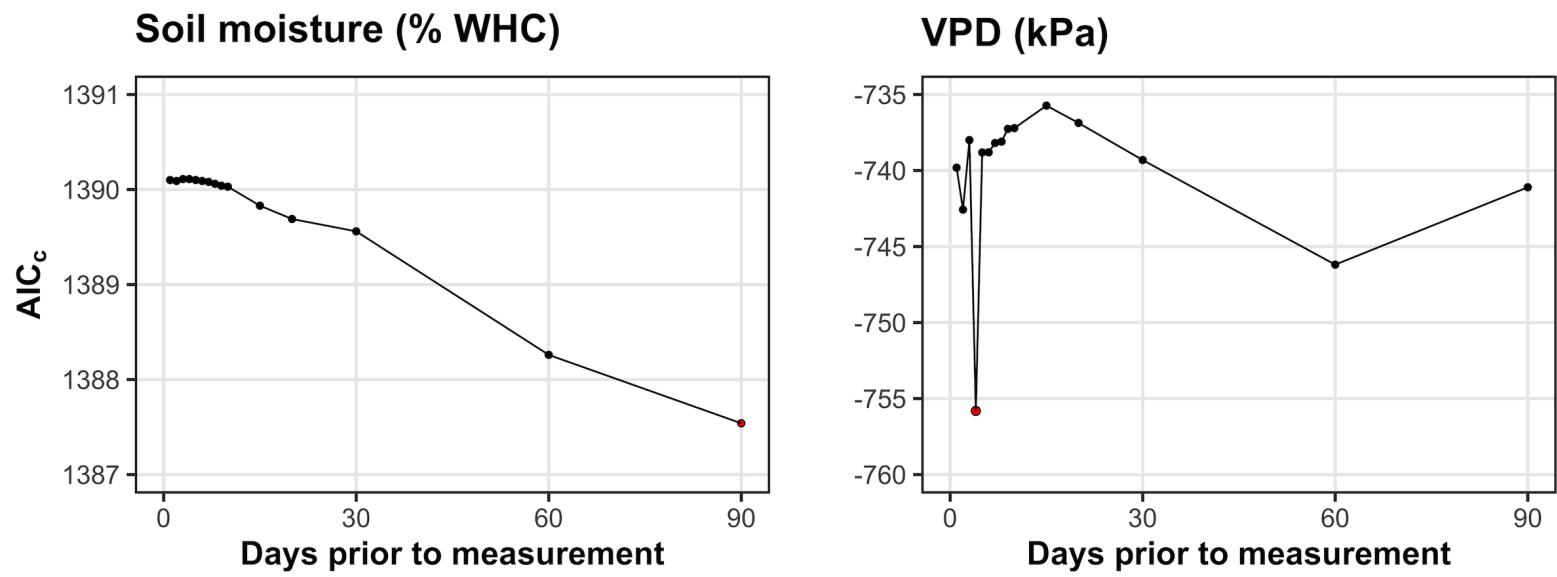

Symbol	Species	Photo. pathway	Growth duration	Growth habit	N-fixer?	Plant functional group	Number sampled
ACAN11	<i>Acaciella angustissima</i>	c3	perennial	forb	yes	c3_legume	3
AMAR2	<i>Ambrosia artemisiifolia</i>	c3	annual	forb	no	c3_nonlegume	25

15	1431.54	0.8401	-768.64	0.0856
20	1431.40	0.8401	-769.77	0.0855
30	1431.23	0.8400	-772.18	0.0853
60	1429.84	0.8391	-779.06	0.0848
90	<b>1429.14</b>	<b>0.8385</b>	-773.99	0.0852

**Figure C1.** Model selection results exploring relevant timescales for soil moisture (left panel) and vapor pressure deficit (right panel). The x-axis indicates the number of days before each site visit and the y-axis notes the corrected Akaike Information Criterion value. The timescale with the lowest AIC<sub>c</sub> value, and therefore most relevant timescale to include in statistical models, is noted as a red point.

CO <sub>2</sub> *I*N	1	-4.95E-04	0.640	0.424

**3709** \*Significance determined using Type II Wald  $\chi^2$  tests ( $\alpha=0.05$ ). P-values less  
**3710** than 0.05 are in bold. Key: df=degrees of freedom;  $\chi^2$ =Wald Type II chi-square  
**3711** test statistic.

**Figure D1.** Relationships between area-based leaf nitrogen content (a), mass-based leaf nitrogen content (b), and leaf mass per unit leaf area (c) measured on the focal leaf used to generate  $A_{net}/C_i$  curves (x-axis) and leaf nitrogen content measured on the leaf used for chlorophyll extractions (y-axis). Blue points refer to leaves grown under ambient CO<sub>2</sub> and red points refer leaves grown under elevated CO<sub>2</sub>. Square points indicate uninoculated pots and circular points indicate inoculated pots. Pearson's correlation coefficient, associated  $p$ -values, and the line of the regression line that described each bivariate are included in the top left corner of each plot. The solid black line visualizes the trend given a 1:1 bivariate relationship.

**Figure D2.** Effects of CO<sub>2</sub>, fertilization, and inoculation on the ratio of whole plant biomass to pot volume. Soil nitrogen fertilization is represented on the x-axis in all panels. Yellow points and trendlines indicate inoculated individuals grown under ambient CO<sub>2</sub>, blue points and trendlines indicate uninoculated individuals grown under ambient CO<sub>2</sub>, red points and trendlines indicate inoculated individuals grown under elevated CO<sub>2</sub>, and grey points indicate uninoculated individuals grown under elevated CO<sub>2</sub>. Solid trendlines indicate regression slopes that are different from zero ( $p<0.05$ ). The dotted horizontal line indicates the point where biomass:pot volume exceeds 1 g L<sup>-1</sup>, and the dashed line indicates the point where biomass:pot volume exceeds 2 g L<sup>-1</sup>.
